Abstract

Legacy paint on publicly-accessible structures in residential areas of Plymouth, UK (a bridge parapet, hospital railings, a goal frame, urban street paving and a telephone kiosk) and local paint-contaminated soils have been analysed for lead and other heavy metals (chromium, zinc and barium) by x-ray fluorescence spectrometry. Lead was detected in all paints analysed ($n = 56$) apart from two fragments of yellow road markings, with maximum concentrations exceeding 300 g kg^{-1}. Soils were contaminated by Pb to varying degrees that depended on the condition and Pb content of the paint applications and the nature and vegetation of the soil, with a maximum concentration of 27 g kg^{-1} and a maximum enrichment factor normalised to grain size and regional baseline soil of 270. While Cr showed no clear contamination in soils that could be attributed to paint, contamination from this source was evident for Zn in soil by the goal frame and for Ba and Zn in soil by the bridge parapet. Application of a physiologically-based extraction test to the soils revealed stomach bioaccessibilities that were variable among the samples and between the metals but that were greatest for Zn and lowest for Cr. With the exception of Cr, bioaccessibility generally decreased in the intestine, with mean intestinal bioaccessibilities relative to total metal of about 6% for Pb and Ba, 0.9% for Cr and 1.6% for Zn. From both a health and environmental perspective, Pb is the heavy metal of greatest concern because of its common occurrence at high concentrations in extant paints, coupled with a relatively high bioaccessibility and well-documented chronic neurotoxicity. Public exposure to Pb in residential areas may arise through direct contact with paint or soil or via the intrusion of contaminated geosolids to the household on shoes or as airborne dust.

Keywords: leaded paint; heavy metals; residential; exterior; soils; bioaccessibility

2

1. Introduction

Because of the well-documented acute and chronic toxicities of Pb, and in particular its neuro-toxicological impacts on young children, contemporary and legacy sources of the metal have come under intense scientific scrutiny and increasingly strict regulation over the past few decades (Wadanambi et al., 2008; Holecy and Mousavi, 2012; Datko-Williams et al., 2014). Despite restrictions on or the phasing out of Pb in most applications, the widespread occurrence of elevated concentrations in soil remains a concern from both an environmental standpoint and a health perspective (Luo et al., 2012; Walraven et al., 2015). In urban and residential settings with no distinctive industrial sources (e.g. from mining, smelting or waste processing or disposal), the principal routes of Pb accumulation in soil are believed to be via the historical combustion of leaded gasoline and the historical use but contemporary removal or weathering of exterior Pb-based paints (Clark et al., 2006; Laidlaw and Filippelli, 2008). More specifically, while leaded gasoline is likely to be the dominant source of Pb in soil in the centres of large cities (Mielke et al., 2008), exterior paint may be the larger source in smaller urban and suburban communities (Clark and Knudsen, 2013). Given that an appreciable percentage of Pb inside the household is derived from outdoor dusts and soils (Laidlaw et al., 2014), exterior paint may also, in many cases, represent a significant, if not the principal source of indoor Pb.

In a recent study conducted within Plymouth, a small (~ 250,000 inhabitants) coastal city in south west England, leaded paint was found to be abundant on a range of publicly-accessible painted structures and street furniture, including bollards, telephone kiosks, pillar boxes, bridge parapets, railings, guttering and playground equipment (Turner and Solman, 2016). Since such structures are common throughout

76 the UK, flaking legacy paint from poorly maintained structures was considered a

77 significant, general source of environmental Pb in the urban and suburban settings

78 and, as such, an important indirect source of Pb to the contemporary residential

79 household.

80

81 The present study builds on these observations by re-visiting selected structures where

82 layering and flaking of leaded paint was evident in order to evaluate the impact of

83 external paint on the contamination of local soils by Pb and other heavy metals.

84 Specifically, the contamination of Pb, Cr, Zn and Ba is estimated from measurements

85 of metals in flaking paints and in local and baseline soils, and the bioaccessibility of

86 these metals in paint-impacted soils is determined using a two-stage physiologically-

87 based extraction test (PBET) that simulates, sequentially, the chemical makeup of the

88 human stomach and intestine.

89

90 **2. Materials and methods**

91 *2.1. Sampling, sample preparation and sample characterisation*

92 Sampling targeted structures accessible to or used by the public and that were located

93 in residential areas within 5 km of the centre of Plymouth or in a small community

94 located on Dartmoor National Park and about 15 km to the north of the city. In

95 Plymouth, paint was sampled in dry weather during October 2016 from one of two

96 panelled 20 m x 1.5 m steel parapets of a road bridge (with no road markings) over a

97 disused railway, the 2-m high wrought iron railings demarking the 500-m perimeter of

98 a hospital, yellow parking lines applied to the paved edge of a residential city street,

99 and one of two ~ 4 m x 1 m steel goal frames in a children's play park. On Dartmoor,

100 paint was sampled in November 2016 from a rectangular, 2.5 m x 1 m cast iron-

101   timbered door K6 telephone kiosk in the village of Dousland (50.5006; -4.0670). All

102   structures were within 20 m of private residences with the exception of the goal

103   frames which were within 15 m of the boundary of a primary school. Up to 10 paint

104   flakes of between ~ 2 and 20 mm in length were retrieved with plastic tweezers from

105   accumulations at the foot of each structure or from painted surfaces where extensive

106   flaking was visible and were stored in specimen bags and in the dark pending

107   analysis.

108

109   Triplicate samples of about 30 g of surficial soil were collected using a plastic spatula

110   on the same occasions as the corresponding paint samples were retrieved and at

111   locations in the immediate vicinity of each structure that were most likely to receive

112   the greatest pedestrian disturbance. Specifically, samples were taken from soils

113   adjacent to the pavement and within 1.5 m of the bridge parapet, railings and road

114   paint, road verge soil about 0.5 m from the access door of the telephone kiosk, and

115   soil at a distance of 0.5 m from the goal frame mouth and where the turf had been

116   most trampled. Where possible, and in order to examine spatial variation in metal

117   contamination, additional soil samples were collected at different distances (up to 5

118   m) from the structures and along an axis that was normal to the main face. Regional

119   baseline soils were collected from an area of a small urban park that was within 10 m

120   of an unpainted section of road (urban roadside baseline), the playing fields adjacent

121   to the children's play park (park baseline) and a roadside verge on Dartmoor that was

122   remote from any residential areas (National Park baseline). After being transported to

123   the laboratory in individual specimen bags, samples were oven-dried in crucibles at

124   105 °C for 24 h before stones, fragments of glass, leaves and other debris were

125   removed. Samples were then sieved through 2 mm and homogenised in a series of

126   agate bowls, each containing five agate milling balls, using a Fritsch planetary mill

127   (model Pulverisette 5) at 300 rpm for 3 min. In a fume cupboard, milled samples were

128   packed into individual polyethylene XRF sample cups (Chemplex series 1400, 21-mm

129   internal diameter) that were collar-sealed with 3.6 μm SpectraCertified Mylar

130   polyester film.

131

132   The pH of at least one soil sample from each site was measured using a Meterlab

133   PHM210 pH meter and Hach pHC2051-8 electrode after 5 g portions of dried material

134   had been equilibrated with 12.5 ml aliquots of deionised water in a series of 50 ml

135   polypropylene centrifuge tubes. Loss on ignition (LOI) was determined on soil

136   samples as a measure of organic content by determining the weight loss of ~ 3 g

137   aliquots of dried material after combustion at 550 ºC for 5 h in a Carbolite AAF1100

138   furnace.

139

140   *2.2. XRF analysis*

141   Paint fragments and homogenised soil samples were analysed in the laboratory using

142   a Niton XL3t 950 He GOLDD+ portable XRF housed in a 4000 cm^3 accessory stand.

143   The heavy metals Pb, Cr, Zn and Ba were the focus of the present study because of

144   their extensive historical use in exterior paints, but Fe, Mn, Ca and Rb were also

145   recorded in soils as elements of geochemical significance. Depending on condition

146   and degree of contamination from the underlying (e.g. rusting) substrate, one or both

147   sides of paint samples were analysed in a low density, plastics mode with thickness

148   correction after sample thickness had been measured using digital callipers.

149   Fragments were suspended above the 10 mm detector window on Mylar film before

150   measurements of 60 s, comprising successive counting periods of 30 s each at 50

151 kV/40 μA (main filter) and 20 kV/100 μA (low filter), both with 3-mm collimation,

152 were activated remotely through a laptop. Spectra were quantified by fundamental

153 parameter coefficients to yield elemental concentrations on a dry weight basis (in μg

154 g^{-1}) and with a measurement counting error of 2σ (95% confidence) that were

155 downloaded to the laptop via Niton data transfer (NDT) software. Regular analysis of

156 two Niton polyethylene discs certified for Pb, Cr and Ba (PE-071-N and PN 180-619)

157 returned concentrations of that were within 5% (Pb and Cr) or 15% (Ba) of reference

158 values, and measurement limits of detection (LOD), defined herein as 3σ for samples

159 of the lowest fluorescence intensities, were about 20, 7, 60 and 400 mg kg^{-1} for Pb, Cr,

160 Zn and Ba, respectively.

161

162 Soil samples contained within polyethylene XRF cups were analysed in a higher

163 density mining mode. Here, cups were placed centrally over the detector window with

164 the collar-sealed Mylar surface face-down, and measurements were conducted for 90

165 s, and without collimation, comprising successive counting periods of 30 s each at 50

166 kV/40 μA (main filter), 20 kV/100 μA (low filter) and 50 kV/40 μA (high filter).

167 Concentrations were downloaded to the laptop as above, with corresponding

168 measurement LODs of about 5 mg kg^{-1} for Pb and Rb, mg kg^{-1} for Cr, Zn, Fe and Mn,

169 and 50 mg kg^{-1} for Ba and Ca. Regular analysis of Sigma-Aldrich RTC loams

170 certified for Pb, Cr and Zn and packed in XRF cups (MSL-100, MSM-100, MSH-100,

171 MSL101, MSM-101 and MSH-101) returned concentrations that were within 10% of

172 reference values.

173

174 *2.3. Physiologically-based extraction test*

175 Soil samples were subject to an in-vitro physiologically based extraction test (PBET)

176 that mimics, sequentially, the chemical conditions in the human stomach and

177 intestine. The method is described in detail by Ruby et al. (1996) and Karadaş and

178 Kara (2011) and was undertaken herein using analytical-grade reagents study

179 purchased from Fluka, Sigma-Aldrich or Fisher. Briefly, the gastric solution was

180 prepared by dissolving 1.25 g porcine pepsin, 0.50 g sodium citrate, 0.50 g sodium

181 malate, 420 μL of lactic acid and 500 μL of acetic acid in to 1 L of Milli-Q water and

182 adjusting the contents to pH 2.5 with concentrated HCl. About 0.5 g of each sample

183 and a solid-free control was combined with 50 mL of gastric solution in a series of

184 screw-capped polypropylene centrifuge tubes that were submerged to just below the

185 lid line in a shaking water bath maintained at 37 °C. After 1 h, 5 mL of each extract

186 was filtered through a 0.45 μm Whatman cellulose acetate filter and acidified with 0.1

187 mL of concentrated HNO_3 before being stored under refrigeration pending analysis

188 ("stomach phase" samples). Meanwhile, and following the compensatory addition of

189 5 mL of gastric solution, the pH of each extract was adjusted to 7 using a saturated

190 $NaHCO_3$ solution and 87.5 mg of bile salts and 25 mg of porcine pancreatin added.

191 The contents were then returned to the water bath and incubated for a further 4 h

192 before 5 mL aliquots were abstracted, filtered and acidified as above. In addition, and

193 before storage under refrigeration (and as "intestine phase" samples), extracts were

194 centrifuged at 3000 rpm for 5 min to remove any protein formed after the introduction

195 of the acid spike to the neutral solutions

196

197 *2.4. PBET analysis*

198 Stomach and intestinal phase extracts arising from the PBETs were analysed for Pb

199 and Zn by inductively coupled plasma-optical emission spectrometry (ICP-OES)

200 using a Thermoscientific iCAP 7400, and for Cr and Ba by collision cell-inductively

201 coupled plasma-mass spectrometry (ICP-MS) using a Thermo X-series II (Thermo

202 Elemental, Winsford UK) with a concentric glass nebuliser and conical spray

203 chamber. Instruments were calibrated using four standards and a blank prepared by

204 serial dilution of CPI International standards in 2% HNO_3, with settings described

205 elsewhere (Turner et al., 2016; Turner et al., 2017) and LODs derived from three

206 standard deviations arising from multiple measurements of the lowest standard of

207 about 10 μg L^{-1} for Pb and Zn and 1 and 5 μg L^{-1} for Cr and Ba, respectively.

208

209 **3. Results and Discussion**

210 *3.1. Paint fragment characteristics and heavy metal content*

211 The structures targeted in the present study are illustrated in Figure 1, while results

212 arising from the analysis of paint fragments ($n = 56$) sampled from each structure are

213 shown in Table 1. Overall, and among the metals studied, Pb was the most pervasive,

214 being detected in all but two cases and at concentrations that always exceeded the US

215 urban abatement action level of 5000 mg kg^{-1} (Turner and Solman, 2016). While Ba

216 was detected in some or all fragments from each structure, Cr and Zn were never

217 detected in paint fragments from the goal frame and street paints, respectively. Other

218 elements that were detected less frequently but not considered further included Bi, Cu,

219 Ni, Sn, Sb and V and, while Fe was present in many samples, its presence was

220 generally attributed to contamination from the underlying metallic or paved substrate.
221

222

223

224

225

Figure 1: The painted structures considered in the present study. (a) The steel parapet of a road bridge over a disused railway, (b) the paved edge of a city street, (c) railings around Plymouth Eye Hospital, (d) the vertical post of a goal frame in a play park, and (e) a telephone kiosk serving a small community on Dartmoor.

The parapets of the road bridge had been overpainted several times and in different colours (but mainly white, grey, blue and lilac) and the surface was heterogeneous and highly crazed. Fragments retrieved were usually multi-layered, with a thickness that ranged from about 0.8 to 1.6 mm, and concentrations of Pb were highly variable, with a maximum content of 300,000 mg kg^{-1} returned for the outer white surface of paint taken directly from the base of the right-hand panel shown in Figure 1a. While the

250   detection of Cr was limited to five paint fragments from the parapet and to

251   concentrations less than 500 mg kg^{-1}, Ba and Zn were present in all fragments

252   analysed, with the highest concentrations (above 10,000 mg kg^{-1} and 100,000 mg kg^{-1},

253   respectively) encountered in bluish-grey and white formulations. These observations

254   are consistent with the occurrence of multiple, historical applications of paint of

255   differing Pb content that include leaded zinc oxide (a mixture of basic lead sulphate

256   and zinc oxide) but not brightly coloured lead chromates, and the pervasive use of Ba

257   (e.g. $BaSO_4$) as a filling agent.

258

259   The hospital railings were rusting throughout, with residual black paint of limited

260   thickness (< 0.1 mm) and layering but that was readily flaking. All paint fragments

261   retrieved contained less variable concentrations of Pb than those on the railway

262   bridge, with an average content of 100,000 mg kg^{-1}, and Cr, Zn and Ba were detected

263   in a limited number of cases and at concentrations below 250 , 5000 and 1000 mg kg^{-1}

264   , respectively. These observations suggest the historical use of a limited number of

265   broadly similar formulations that were not based on chromates or leaded zinc oxide

266   but that were likely comprised of white lead ($2PbCO_3 \cdot Pb(OH)_2$) that had undergone

267   darkening and conversion to lead sulphide by the long-term contact with SO_2 in urban

268   air.

269

270   The play park goal frame had multiple layers of white or cream paint that had been

271   eroded to the substrate in parts, with the distribution of paint-free areas on the cross

272   bar consistent with the gradual, long-term abrasion caused by children swinging on

273   the structure. Lead concentrations in the paint fragments were variable and, while Cr

274   was never detected, Zn was always present at concentrations up to 100,000 mg kg^{-1},

275   suggesting that leaded zinc oxide was the principal Pb-based pigment present.

276   Although fragments were often layered (and around 0.1 to 0.2 mm thick), it was

277   unclear whether the various applications contained different concentrations of Pb or

278   leaded paints had been diluted with more recent lead-free formulations.

279

280   Most yellow markings at the roadside throughout the regions of the city inspected

281   appeared to have been successively overpainted, especially where the paved surface

282   was irregular, with older applications usually brighter and characterised by a

283   distinctive orange hue. Fragments retrieved from the crumbling road markings along

284   the residential street were typically between 1 and 3 mm thick and contained Pb

285   concentrations of a few thousand $\mu g\ g^{-1}$ with the exception of two markedly paler

286   samples derived from the top painted layer where the metal was not detected. While

287   Ba was present in all fragments and at concentrations of a few thousand $mg\ kg^{-1}$, Zn

288   was never detected and Cr was only detected whenever Pb was present.

289   Concentrations of the latter metals were highly correlated ($r = 0.957$, $p < 0.01$; $n = 8$),

290   with a slope defining the best-fit line forced through the origin of 4.62 and close to

291   that defining the mass ratio of Pb:Cr ($= 3.98$) in the yellow pigment, lead chromate

292   ($PbCrO_4$). These observations are consistent with the historical use of lead chromate

293   in road marking paints but the more recent use of safer (albeit less brightly coloured)

294   alternative pigments.

295

296   Paint fragments derived from the telephone kiosk on Dartmoor were different shades

297   of red-orange and of variable thickness (0.05 to 1.3 mm) and layering, with Pb

298   occurring at concentrations in excess of 40,000 $mg\ kg^{-1}$ throughout. Chromium, Ba

299   and Zn were detected in all fragments and over a range of concentrations that

300   averaged 13,000, 22,000 and 4000 mg kg^{-1}, respectively. Lead and Cr concentrations

301   were highly correlated ($r = 0.962$; $p < 0.01$; $n = 10$) but a best-fit line could only define

302   the data when an intercept was included ($[Pb] = 1.713[Cr] + 50,400$). The gradient of

303   the relationship suggests the presence of a lead chromate of different Pb:Cr

304   stoichiometry to that in the yellow road line paint above and/or the presence of an

305   additional compound of Cr. The former is likely molybdate sulphate red

306   ($Pb(Cr,S,Mo)O_4$), an assertion supported by the distinctive colour of phone boxes and

307   strong fluorescent peaks at 17.48 keV (Mo-Kα1) and 19.61 (Mo-Kβ1) in the paint

308   samples, while the ubiquity of Zn suggests the latter may be the anti-corrosion primer

309   and pigment, zinc chromate. The intercept of the Pb-Cr relationship also indicates the

310   presence of a leaded compound containing about 5% Pb but that does not contain Cr,

311   possibly the red, rust-proof primer, lead (II,IV) oxide ($2PbO \cdot PbO_2$).

312

313   Table 1: Number of analyses performed on paint fragments from each structure, along

314   with the number of cases in which Pb, Cr, Zn and Ba were detected and summary

315   statistics for their concentrations in mg kg^{-1} .

317

318   *3.2. Soil characteristics and heavy metal content and enrichment*

319   The geochemical characteristics of the soil samples are shown in Table 2. LOI ranges

320   from about 10% in the park baseline soil to 30% in soil in the vicinity of the hospital

321   railings, and pH is about 7 within the city of Plymouth and 6.5 on Dartmoor. Of the

322   geochemically-relevant metals reported, Fe exhibits clear evidence of contamination

323   by paint particles or the underlying metallic substrate and Ca exhibits the greatest

324   variation in concentration among the sites investigated.

325 Table 2: Geochemical characteristics of the soil samples in the vicinity of the various

326 painted structures and at the baseline locations (n = 1 or 3; DNP = Dartmoor National

327 Park). Note, LOI = loss on ignition in % and metal concentrations are given in mg kg^{-1}

328 ^{1}.

329

330

331 The mean concentrations of Pb, Cr, Zn and Ba in the soil samples are shown in Table

332 3. In all cases, Pb concentrations in the vicinity of the painted structures are

333 considerably higher than the corresponding baseline concentrations, with soils

334 adjacent to the road bridge parapet and goal frame exceeding the urban and park

335 baselines by factors of 100 and 20, respectively. The mean concentration in the bridge

336 parapet soil is more than double the highest concentration of Pb measured in topsoils

337 throughout England (Defra, 2012) and is comparable with the highest concentrations

338 reported for Pb in US soils (Datko-Williams et al., 2014). While soil contamination by

339 the remaining metals is not as pervasive, it is evident where mean concentrations are

340 highest in the local paint formulations; specifically, Ba exhibits contamination in soils

341 adjacent to the bridge parapet and telephone kiosk and Zn in soils by the parapet and

342 goal frame.

343

344 The fractional contribution of Pb derived from paint particles to the local soil Pb

345 burden, f_p, was estimated from mass balance as follows:

346

347 $f_p = ([Pb]_s-[Pb]_b)/([Pb]_p - [Pb]_b)$ (1)

348

349 where subscripts p, s and b refer to paint, contaminated soil and baseline soil,

350 respectively, and concentrations are defined by mean values reported in Tables 1 and

351 2. Results of the calculations indicate an estimated contribution of Pb from paint

352 ranging from < 0.5% for the soil by the hospital railings to over 20% for soils by the

353 bridge parapets and the street lines. Note that equivalent calculations performed for

354 Cr, Zn and Ba were not considered meaningful because concentration differences in

355 the numerator or denominator were often small or negative (that is, concentrations in

356 contaminated soils or paint fragments were close to concentrations in the

357 corresponding baselines).

358

359 One problem with the mass balance approach above is that the heavy metal content of

360 the source material is heterogeneous, largely because of the presence of multiple

361 applications that are weathered differentially; this results in a range in paint metal

362 concentration that usually spans more than an order of magnitude for each structure.

363 Moreover, as an evaluation of local contamination, mass balance does not

364 acknowledge potential metal leaching from residual, historical paint on the structure

365 itself. To this end, a better measure of soil contamination is one that compares metal

366 concentrations in contaminated and baseline soils after compensation for

367 granulometry. Correction for grain size, or the propensity of soil particles to adsorb

368   metals, requires normalisation of concentrations with respect to an element whose

369   abundance reflects particle size, and that is conservative (or insensitive to changing

370   environmental conditions), has no significant local contamination sources and is

371   readily measurable. Since Rb satisfies these criteria, substituting for K in fine-grained

372   clays yet often absent in coarser natural particles, having very little influence by

373   anthropogenic activity and being routinely analysed by XRF (Rae, 1995),

374   concentrations measured in the soils and reported in Table 3 have been used to

375   calculate enrichment factors (EFs) for each heavy metal (Me):

376

377        $EF = ([Me]_s/[Rb]_s)([Me]_b/[Rb]_b)^{-1}$ (2)

378

379   Values of EF, shown in Table 4, can be partly understood in terms of the metal

380   concentrations in the source material and the condition of the applications. For

381   instance, high enrichment of Pb, Zn and Ba is encountered in the soil contaminated by

382   bridge parapet paint containing relatively high concentrations of these metals and that

383   was flaking extensively; conversely, enrichment below 0.5 occurs for Cr in goal frame

384   soil where the metal was never detected in paints derived from the corresponding

385   structure. In other cases, however, additional, confounding factors also appear to be

386   significant. For example, despite railing paint having a mean Pb concentration of

387   100,000 mg kg^{-1}, local soil enrichment was the lowest among the samples considered,

388   an effect we attribute to the dense coverage of unkempt vegetation around the hospital

389   that acts as protection from and aids dispersion of flaking paint particles.

390

391 Table 3: Concentrations of Pb, Cr, Zn and Ba (in mg kg^{-1} ; n = 3) in the soil samples

392 in the vicinity of the various painted structures and at the baseline locations (DNP =

393 Dartmoor National Park).

399

400

401
Figure 2: Heavy metal enrichment factors in soils sampled at different distances from

the door of the telephone kiosk.

404

EFs were also applied to examine the spatial dispersion of paint-derived Pb, Cr, Zn

and Ba in soils in the vicinity of poorly-maintained structures. Results are exemplified

in Figure 2 for soils collected at different distances from the telephone kiosk on

Dartmoor, where all heavy metals were present in the paint at relatively high

concentrations but additional anthropogenic sources are absent. Here, values of EF

reveal an exponential reduction for all metals to a distance of 3 to 5 m, a distribution

that is characteristic of a point-source of particulate metal, like paint, rather than a

diffuse one (Clark and Knudsen, 2013; Thompson et al., 2014).

413

3.3. Comparison of Pb and Cr concentrations in soils with SGVs

415   Regarding human health and environmental protection, various countries and

416   organisations have devised < 2 mm but non-normalised soil standards for heavy metal

417   concentrations (CCME, 1999; Walraven et al., 2015; Vodyanitskii, 2016). In the UK,

418   generic soil guideline values (SGVs) for both Pb and Cr were derived by the

419   Environment Agency (2002) using the Contaminated Land Exposure Assessment

420   (CLEA) model for three land uses. Specifically, values for Pb were 450 mg kg^{-1} for

421   allotments and residential soils, both with and without plant uptake, and 750 mg kg^{-1}

422   for commercial-industrial soils; for Cr, values were 130 mg kg^{-1} and 200 mg kg^{-1} for

423   residential soils with and without plant uptake, respectively, 130 mg kg^{-1} for

424   allotments and 5000 mg kg^{-1} for commercial or industrial soils. SGVs were designed

425   to represent intervention values which, if exceeded, posed potentially unacceptable

426   risks to site users and may require investigation or remedial action. The results of the

427   present study indicate localised exceedance of the residential SGVs for Pb in all paint-

428   contaminated soils, and exceedance of the commercial-industrial SGV in all but one

429   case; in contrast, Cr concentrations in soils never exceed residential without plant

430   uptake and commercial-industrial SGVs. For reasons that are unclear, however, the

431   original CLEA model was withdrawn in 2006, with new SGVs subsequently issued

432   by the Environment Agency (2009) and based on updated software that excluded both

433   Pb and Cr. With respect to Pb, more recent evidence for neurotoxicity at lower

434   exposure levels was cited as status for 'reconsideration', but for Cr, a rationale for

435   withdrawal of SGVs does not appear to have been provided.

436

437   *3.4. Heavy metal bioaccessibility in soils*

438   Aside from their absolute concentrations, critical to the health risks of heavy metals in

439   contaminated soils is their bioaccessibility, or their propensity to migrate from the

440   ingested or inhaled material into physiological solutions. In this study, a two-stage,

441   sequential PBET was used to evaluate the bioaccessibilities of Pb, Cr, Zn and Ba in

442   the < 2 mm fraction of soils in the human stomach and intestine, and results, on both a

443   concentration and percentage (relative to total metal) basis are illustrated in Figure 3.

444

445   In the stomach phase, the bioaccessibility of Pb ranges from about 3 to 18%, with

446   concentrations varying from around 3 mg kg^{-1} in two baselines to over 3000 mg kg^{-1}

447   (and well in excess of SGVs based on total Pb) in the bridge parapet soil. In most

448   cases, bioaccessibility is lower in the intestine than in the stomach because the higher

449   pH in the former favours the re-adsorption of Pb^{2+} ions to the soil particle surface and

450   the precipitation of relatively insoluble Pb species (Turner and Ip, 2007). The

451   percentage bioaccessibility of the metal in either phase of the PBET does not appear

452   to be directly related to its total concentration in the matrix, nor to the geochemical

453   characteristics of the soil. Rather, it is likely that accessibility is dependent on the

454   nature and degree of metal-soil particle interactions, which themselves are controlled

455   by the age and condition of the applications and the solubilities of the component

456   leaded pigments (Walraven et al., 2015).

457

458   Chromium bioaccessibility is considerably lower than that of Pb, presumably because

459   of the relatively poor solubility of chromate pigments, with percentages never

460   exceeding 2.5 in either of the simulated PBET phases but that were higher in the

461   intestine than the stomach in five cases. The latter effect may be attributed to the

462   existence of negatively charged, polyatomic forms of Cr(VI) whose desorption from

463   the contaminated soil matrix is predicted to be promoted in the higher pH

464   environment of the intestine (Villalobos et al., 2001). Zinc exhibits the greatest

465   percentage accessibility in the stomach phase among the metals studied (between

466   about 15 and 45%). However, the higher pH of the simulated intestine ensures that,

467   through readsorption of Zn^{2+} ions to the soil matrix, intestinal accessibility never

468   exceeds 3% of total Zn. While Ba exhibits lower percentage stomach

469   bioaccessibilities than Zn, less readsorption of Ba^{2+} ions at higher pH results in

470   intestinal accessibilities that are generally greater (and by up to an order of

471   magnitude) than corresponding values for Zn.

472

473   Given that absorption takes place primarily in the intestinal epithelium, the heavy

474   metal concentration remaining in the simulated intestine may provide the most

475   relevant estimate of its bioavailability, or the fraction of total metal that reaches the

476   systemic circulation. In the present study, the mean percentage intestinal accessibility

477   in the five contaminated soils was in the order: Pb, Ba (~ 6) > Zn (1.6) > Cr (0.9);

478   with variations in precise accessibilities reflecting differences in the nature and age of

479   the contaminating paint, the type and characteristics of the local soil, and the presence

480   of additional, and more diffuse metal sources.

481
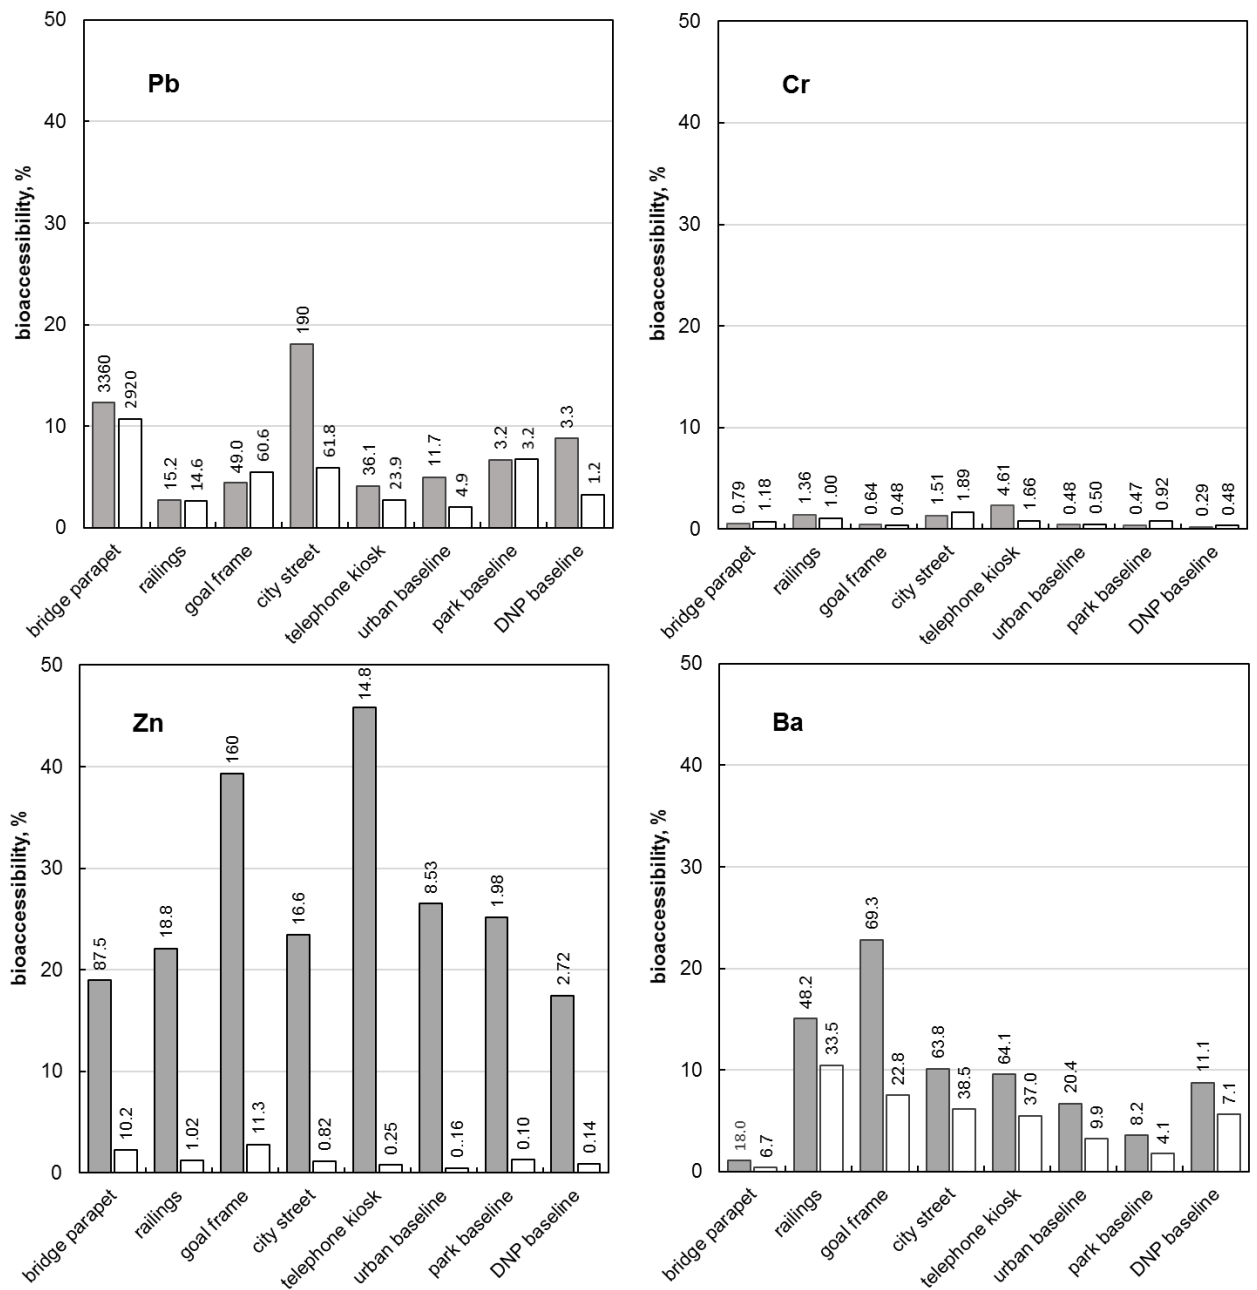

Figure 3: Percentage stomach and intestinal bioaccessibilities (shaded and white bars,

respectively) of Pb, Cr, Zn and Ba in the soil samples. Annotated are the

corresponding bioaccessible concentrations in mg kg^{-1}.

3.5. General discussion

This study has shown that legacy leaded paint is a characteristic of functional

structures in residential areas of south west England. While the painted areas

489   themselves are relatively small, the structures are commonplace throughout the UK

490   and are generally accessible to the public and close to sensitive receptors (houses,

491   schools, hospitals). For example, there are about 11,000 K6 telephone kiosks in

492   service throughout the UK that are owned by British Telecom (BT) and over 28,000

493   railway bridges managed by Network Rail. With little requirement or incentive to

494   maintain the décor of telephone kiosks that have seen a rapid decline in usage, or to

495   repair the extant, metallic components of disused railway bridges, a consequence is

496   extensive flaking or crumbling from overpainted layers that affords a direct means of

497   contaminating local soil and road dusts with heavy metals. Contamination of surface

498   runoff, ground water and storm waters may then occur through the dissolution of

499   metals from soil and dust into rainwater, an effect accentuated by low pH and the

500   presence of complexants (Davis and Burns, 1999; Wu and Kim, 2017).

501

502   From a health perspective, and based on its known chronic neurotoxicity and the

503   concentrations and intestinal accessibilities in contaminated soils, Pb is the metal of

504   greatest concern amongst those considered in this study. Although Pb contamination

505   is localised, there is a direct risk of metal exposure to children in turfed play parks

506   containing painted equipment through the inadvertent or deliberate ingestion of

507   contaminated soil while playing (Stanek et al., 2012). More generally, the location of

508   poorly maintained structures in residential areas poses risks of Pb exposure indoors

509   from intruding airborne dust generated through resuspension by wind and moving

510   traffic, and by material tracked-in on clothes and shoes and on the feet of family pets

511   (Laidlaw et al., 2014); here, entry into the household setting is likely to be accentuated

512   in the summer months when soil is drier and looser and properties are more ventilated,

513   resulting in a distinct seasonal variation in exposure. Flaking paint itself also poses a

514   direct risk of Pb exposure to contractors maintaining, repainting, restoring or

515   demolishing structures and affords an additional indirect means by which the metal

516   may be introduced into the household via clothing, hair or shoes (Virji et al., 2009).

517   We note that a recent Office of Rail Regulation (2014) report refers to six cases of

518   employee absence through elevated blood Pb levels over a three year period, and that

519   all personnel were working on refurbishment of railway bridges or stations involving

520   cutting and/or surface treatment of painted surfaces.

521

522   We contacted the stakeholders or responsible authorities in respect of the types of

523   structures considered in the present study and received responses that were generally

524   proactive, but only localised and short-term. For example, BT either removed or

525   repainted telephone kiosks within the city of Plymouth, while Network Rail

526   acknowledged that there was a problem with leaded paint and suggested that the

527   particular bridge we identified may be prioritised for repainting. Plymouth City

528   Council decommissioned a number of playground facilities known to contain leaded

529   paint after being alerted to findings from a more specific, earlier survey (Turner et al.,

530   2016), but were not receptive to a broader investigation or remediation of the general

531   problem.
