ABSTRACT

Aims To establish the relationship between exercise training and clinical outcomes in people with type I diabetes.

Methods Studies were identified through a MEDLINE search strategy, Cochrane Controlled Trials Registry, CINAHL, SPORTDiscus and Science Citation Index. The search strategy included a mix of key concepts related to exercise training; type 1 diabetes; glycaemic control for trials of exercise training in people with type 1 diabetes. Searches were limited to prospective randomized or controlled trials of exercise training in humans with type 1 diabetes lasting 12 weeks or more.

Results In exercised adults there were significant improvements in body mass Mean Difference (MD): -2.20 kg, 95% Confidence Interval (CI) -3.79 -0.61, p=0.007; body mass index (BMI) MD: -0.39 kg/m², 95% CI -0.75 -0.02, p=0.04; Peak VO₂ MD: 4.08 ml/kg/min, 95% CI 2.18 5.98, p<0.0001; and, low-density lipoprotein cholesterol (LDL) MD: -0.21 mmol/L, 95% CI -0.33 -0.08, p=0.002. In exercised children there were significant improvements in insulin dose MD: -0.23 IU/kg, 95% CI -0.37 -0.09, p=0.002; waist circumference MD: -5.40 cm, 95% CI -8.45 -2.35, p=0.0005; LDL MD: -0.31 mmol/L, 95% CI -0.55 -0.06, p=0.02; and, triglycerides MD: -0.21 mmol/L, 95% CI -0.42 -0.0, p=0.04. There were no significant changes in glycosylated haemoglobin (HbA1C%), fasting blood glucose, resting heart rate, resting systolic blood pressure or high density lipoproteins in either group.

Conclusions Exercise training improves some markers of type 1 diabetes severity; particularly body mass, BMI, Peak VO₂ and LDL in adults and insulin dose, waist circumference, LDL and triglycerides in children.

Keywords
Exercise Training, Meta-Analysis, Type I diabetes

Abbreviations

Body Mass Index (BMI)
CI – Confidence Interval
HDL – High Density Lipoproteins
LDL – Low Density Lipoproteins
HbA1C% - Glycosylated Hemoglobin
% HR_{max} - Heart Rate Peak
% VO_{2} Peak - Percentage of Peak Oxygen Uptake
MD – Mean Difference

INTRODUCTION

The clinically beneficial effects of lifestyle interventions have been shown in meta-analyses in people with type II diabetes [1]. Substantial pooled data has demonstrated improvements in peak VO_{2} [2] and glycaemic control [3] in individuals with type II diabetes. In the general population, high intensity interval training has been shown to be more effective in regulating glucose than continuous training at lower intensity [4]. Moreover, high intensity exercise training has been shown to be superior to lower intensity exercise for improving cardiorespiratory fitness (peak VO_{2}) in heart failure patients [5-7]. Evidence of beneficial effects of regular exercise training is sparse for people with Type I Diabetes (T1D).

While few trials of exercise training in T1D exits, it has been demonstrated that increased physical activity is associated with an increased life expectancy and a lower risk of
complications in these patients [8]. More alarmingly an estimated 60% of adults with T1D do not undertake the recommended 150 minutes of weekly levels of physical activity at moderate (50-70% HRmax) to vigorous (>70% HRmax) intensity [9]. However, the clinical implications of these guidelines are contentious and their effect on clinical outcomes are yet to be established.

Poor compliance rate may be at least be partially explained by fear of an induced hypoglycaemic episode and fitness levels [10]. While it has been shown that educational interventions improve the associated fear of exercise induced hypoglycaemic event, no appropriate evidence addresses the efficacy of the current recommendations and their relationship to the clinical outcomes [10]. With T1D affecting adult, adolescent and paediatric groups, the recommendations for children and adults in terms of physical activity are very similar. We focused our work on establishing the clinical efficacy of the recommendation for physical activity in all patients with Type 1 Diabetes.

We conducted a systematic analysis of all clinical randomized, controlled, aerobic exercise training trials in people with type I diabetes. We aimed, via systematic review, to establish the relationship between physical activity and its effect on clinical markers of glycaemic control and cardiorespiratory fitness. Secondly, we wished to establish if exercise training program parameters affected the size of change in clinical outcome measures. Finally, we examined if our findings aligned with the current recommendations for physical activity.

**MATERIALS AND METHODS**

*Search Strategy*
Studies were identified through a MEDLINE search strategy (1985 to Aug 4, 2016), Cochrane Controlled Trials Registry (1966 to Aug 4, 2016), CINAHL, SPORTDiscus and Science Citation Index. The search strategy included a mix of MeSH and free text terms for the key concepts related to exercise training, type 1 diabetes and glycaemic control for clinical trials of exercise training in people with type 1 diabetes (see PubMed search strategy in Supplementary file). We considered all types of physical training. Studies were included if patients exhibited a diagnosis of type 1 diabetes. Searches were limited to prospective randomized or controlled trials of exercise training in humans, lasting 12 weeks or more. No restrictions were placed on the year, or language, of publication. Reference list of papers and latest editions of relevant journals which were not available online were scrutinised for new references. Full articles were read and assessed by two reviewers (DJ and CO) for relevance and study eligibility. Disagreements on methodology were resolved by discussion, a third reviewer (NS) adjudicated over any disputes. Study authors were contacted and requested to provide further data if required.

Study selection

Included studies were randomized controlled trials of exercise training in people with type 1 diabetes. All published studies included in this systematic review were comparisons between intervention groups and a sedentary control.

In addition to the studies identified through database searching, reference lists of identified studies were scrutinized. Only the principal study with the greatest number of subjects was included where multiple publications existed from the same dataset. After initial screening we removed over-lapping, duplicates, duplicate data and irrelevant articles such as editorials and discussion papers that did not match the inclusion criteria. We excluded studies where
the control group received additional intervention or did not have type 1 diabetes, non-relevant studies; and those reporting only acute exercise testing responses. We excluded studies from specific analyses if incomplete data was reported and the authors did not respond to our requests to provide missing data.

**Outcomes measures**

We recorded the following data; percentage change in HbA1c%, BMI, body mass, Waist Circumference, peak VO₂, resting heart rate, resting systolic blood pressure, fasting blood glucose, low density lipoproteins (LDL), high density lipoproteins (HDL), triglycerides and daily insulin dose. We also recorded exercise training frequency, intensity, duration per-session, length of exercise program, participant exercise adherence and completion rates.

**Data Synthesis**

From extracted data we calculated patient-hours of exercise training, mean difference change in outcome measures and medical events.

**Assessment of study quality**

We assessed study quality with regard to: eligibility criteria specified, random allocation of participants, allocation concealed, similarity groups at baseline, assessors blinded, outcome measures assessed in 85% of participants and intention to treat analysis. The study quality was assessed according to the validated TESTex scale which has a maximum score of 15 [11].

**Data Synthesis**
Revman 5.3 (Nordic Cochrane Centre, Denmark) was used to complete the meta-analysis and generate forest plots. Pooled data are presented as mean differences. A minimum of three intervention groups was required for forest plots. Some studies used more than one intervention group, but the same people were only represented once in our forest plots.

Meta-analyses were completed for continuous data by using the change in the mean and standard deviation of outcome measures. It is an accepted practice to only use post intervention data for meta-analysis but this method assumes that random allocation of participants always creates intervention groups matched at baseline for age, disease severity etc. Change in post intervention mean was calculated by subtracting baseline from post intervention values. Data required was either (i) 95% confidence interval data for pre-post intervention change for each group or when this was unavailable (ii) actual p values for pre-post intervention change for each group or if only the level of statistical significance was available (iii) we used default p values e.g. p<0.05 becomes p=0.049, p<0.01 becomes P=0.0099 and p = not significant becomes p=0.05.

Where appropriate data was divided into subgroups according to adults and children (under 18 years); and, pre and post 2000 studies. This was considered important because of developmental changes to insulin formulations and insulin delivery technologies have evolved a great deal over the past two decades. We believe these differences may lead to differences in key parameters such as peak VO\(_2\) and because of possible chronological variations in the technique used to measure some of the variables e.g. peak VO\(_2\). In many cases there was insufficient studies/intervention groups to facilitate a complete analysis of all the experimental groups.

**Heterogeneity**
Heterogeneity was quantified using the $I^2$ test [12], as it does not inherently depend upon the number of studies considered. $I^2$ values range from 0% (homogeneity) to 100% (greater heterogeneity); a CI that does not include 0% indicates that the hypothesis of homogeneity is rejected, and an inference of heterogeneity is merited [12]. A random effects model was used throughout.

Publication Bias

Egger plots [13] were provided to assess the risk of publication bias (see supplementary files).

RESULTS

Our initial search identified 36 manuscripts. After removal of duplicates, 33 studies remained, of which 14 were not randomised controlled trials. Out of the remaining 19 studies, two were excluded due to a lack of proper randomisation, 2 were excluded due to a control group consisting of those without diabetes, and another study was excluded for a non-exercise intervention. This left 14 included studies [10, 14-27] for analysis. The search details are provided in the CONSORT Statement, Figure 1.

Our analysis of the 15 studies (16 intervention groups) totalled 596 participants; 360 from exercise groups and 236 from control groups. Five of the studies involved adults and 6 of the studies were completed before 2000. The studies contain data from 9,251 patient-hours of exercise training. Studies ranged in duration from 12-26 weeks (average 18.7 weeks, median 16 weeks), and 1-7 weekly exercise sessions (median =3) and session duration ranged from 20-120 minutes (median =47.5). Table 1. Summarizes the details of the included studies.
Meta-Analyses

All forest plots can be seen in the supplementary file.

HbA1C%

Eleven intervention groups provided data on HbA1C% of which 4 intervention groups were in adults with the remainder in children and 4 studies were carried out prior to 2000. Results show that there was no significant difference between exercise and control for either adults MD: -0.08%, 95% CI: -0.38, 0.22; p = 0.6 (Chi² = 13.96, df = 3, p = 0.003; I² = 79%); or, children MD: -0.27%, 95% CI -0.73, 0.19; p = 0.25 (Chi² = 22.97, df = 6, p = 0.0008; I² = 74%). There was also no significant difference between studies that were performed post-2000 MD -0.11%, 95% CI -0.37, 0.16; p = 0.43 (Chi² = 32.79, df = 6, p = 0.0001; I² = 82%); and, studies that were performed pre-2000 MD: -0.15%, 95% CI -0.76, 0.46; p = 0.62 (Chi² = 6.18, df = 3, p = 0.10; I² = 51%).

Total daily insulin dose (IU/kg)

There was insufficient studies to pool data for total daily insulin dose in adults and in pre-2000 studies. Four intervention groups studied this parameter in children, which showed that exercise significantly lowered the total daily insulin dose MD: -0.23 IU/kg, 95% CI -0.37 -0.09; p = 0.002 (Chi² = 23.48, df = 3, p < 0.0001; I² = 87%). A similar significantly lowering effect with exercise was measured in the 6 post-2000 intervention groups, where MD: -0.16, 95% CI -0.26, -0.05; p = 0.003 (Chi² = 84.46, df = 5, p < 00001; I² = 94%).

Fasting blood glucose in children (mmol/L)
There was only sufficient intervention groups (3) to perform data pooling on fasting blood glucose in children. Results show that there was no significant effect of exercise $\text{MD: } -0.71 \text{ mmol/L, 95% CI } -1.94, 0.52; p = 0.26 \text{ (Chi}^2 = 19.18, \text{df} = 2, p < 0.0001; I^2 = 90\%)$.

**Body mass (kg)**

Sufficient data was available to perform data pooling in adults (3 intervention groups), children (4 intervention groups) and post-2000 (5 intervention groups) studies. Results show that exercise significantly reduced body mass in adults $\text{MD: } -2.20 \text{ kg, 95% CI } -3.79, -0.61; p = 0.007 \text{ (Chi}^2 = 5.12, \text{df} = 2, p = 0.08; I^2 = 61\%)$. In contrast, exercise significantly increased body mass in children $\text{MD: } 0.95 \text{ kg, 95% CI } 0.17, 1.73; p = 0.02 \text{ (Chi}^2 = 2.12, \text{df} = 3, p = 0.55, I^2 = 0\%)$. Exercise did not significantly affect body mass in post-2000 studies $\text{MD: } -0.54, 95\% \text{ CI } -2.1, 1.02; p = 0.5 \text{ (Chi}^2 = 17.95, \text{df} = 4, p = 0.001; I^2 = 78\%)$.

**BMI (kg/m²)**

Sufficient data was available to perform data pooling in adults (3 intervention groups), children (3 intervention groups) and post-2000 (6 intervention groups) studies. Results show that exercise significantly reduced BMI in adults $\text{MD: } -0.39 \text{ kg/m}^2, 95\% \text{ CI } -0.75, -0.02; p = 0.04 \text{ (Chi}^2 = 7.54, \text{df} = 2, p = 0.02; I^2 = 73\%)$; but not in children $\text{MD: } 0.29 \text{ kg/m}^2, 95\% \text{ CI } -0.03, 0.61; p = 0.07 \text{ (Chi}^2 = 1.92, \text{df} = 2, p = 0.38; I^2 = 0\%)$. Exercise did not exert any significant effect in post-2000 studies $\text{MD: } -0.11 \text{ kg/m}^2, 95\% \text{ CI } -0.43, 0.21; p = 0.5 \text{ (Chi}^2 = 18.83, \text{df} = 5, p = 0.002; I^2 = 73\%)$.

**Waist circumference in children (cm)**

Three intervention groups reported waist circumference in children and in post-2000 studies. In children, results show that exercise significantly reduced waist circumference $\text{MD: } -5.4$
cm, 95% CI -8.45, -2.35; p = 0.0005 (Chi² = 92.45, df = 2; p < 0.00001; I² = 98%). There was insufficient data to perform pooling for adults and pre-2000 studies.

**Peak VO₂ (ml/kg/min)**

Peak VO₂ was reported in 4 adult studies and 3 studies on children. Results show that exercise significantly increased peak VO₂ in adults MD: 4.08 ml.kg⁻¹.min⁻¹, 95% CI 2.18, 5.98; p < 0.0001 (Chi² = 4.88, df = 3, p = 0.18; I² = 39%); but, not in children MD: 1.95 ml.kg⁻¹.min⁻¹, 95% CI 0.04, 3.85; p = 0.05 (Chi² = 0.96, df = 2, p = 0.62; I² = 0%). Four pre-2000 and 3 post-2000 studies reported peak VO₂. Results show exercise significantly increased peak VO₂ in both pre-2000 studies MD: 2.22 ml.kg⁻¹.min⁻¹, 95% CI 0.88, 3.57; p = 0.001 (Chi² = 1.13, df = 3, p = 0.77; I² = 0%; and post-2000 studies MD: 3.1 ml.kg⁻¹.min⁻¹, 95% CI 0.29, 5.91; p = 0.03 (Chi² = 3.47, df = 2; p = 0.18; I² = 42%).

**Resting heart rate in adults (bpm)**

There were insufficient data for pooling in children, pre-2000 and post-2000 studies regarding resting heart rate. Three studies reported resting heart rate in adults. Results show there was no significant difference in exercise compared to control MD: -4.11 bpm, 95% CI -9.01, 0.8; p = 0.1 (Chi² = 7.24, df = 2, p = 0.03; I² = 72%).

**Resting systolic blood pressure in post-2000 studies (mmHg)**

There were insufficient data for pooling in adults, children and pre-2000 studies. Results show that there was no significant difference in exercise compared to control MD: -3.89 mmHg, 95% CI -11.61, 3.82; p = 0.32 (Chi² = 0.2, df = 2, p = 0.91; I² = 0%).

**LDL (mmol/L)**
LDL was reported in 4 adults studies and in 3 (4 intervention groups) studies in children.

Exercise significantly reduced LDL in both adults MD: -0.21 mmol/L, 95% CI -0.33, -0.08; p = 0.002 (Chi$^2$ = 1.08, df = 3, p = 0.78; I$^2$ = 0%); and, in children MD: -0.31 mmol/L, 95% CI -0.55, -0.06; p = 0.02 (Chi$^2$ = 8.75, df = 3, p = 0.03; I$^2$ = 66%). LDL was also reported in 6 intervention groups post-2000. Results show that exercise led to a significant reduction in LDL MD: -0.24 mmol/L, 95% CI -0.39, -0.09; p = 0.002 (Chi$^2$ = 9.23, df = 5, p = 0.10; I$^2$ = 48%).

**HDL (mmol/L)**

HDL was reported in 4 adults studies and 3 (4 intervention groups) studies in children.

Exercise did not affect the plasma HDL concentration in either adults MD: 0.01 mmol/L, 95% CI -0.08, 0.10; p = 0.86 (Chi$^2$ = 10.86, df = 3, p = 0.01; I$^2$ = 72%); or children MD: 0.15 mmol/L, 95% CI -0.07, 0.37; p = 0.17 (Chi$^2$ = 22.13, df = 3, p < 0.0001; I$^2$ = 86%). HDL was also reported in 5 (6 intervention groups) post 2000 studies, where exercise also did not affect the plasma HDL concentration MD: 0.1 mmol/L, 95% CI -0.07, 0.28; p = 0.26 (Chi$^2$ = 48.35, df = 5, p < 0.00001; I$^2$ = 90%).

**Triglycerides (mmol/L)**

Triglycerides were reported in 4 adult studies and 3 (4 intervention groups) studies in children. Exercise did not affect triglycerides in adults MD: -0.1 mmol/L, 95% CI -0.31, 0.11; p = 0.33 (Chi$^2$ = 26.27, df = 3, p < 0.00001; I$^2$ = 89%). In contrast, exercise significantly reduced triglycerides in children MD: -0.21 mmol/L, 95% CI -0.42, -0.01; p = 0.04 (Chi$^2$ = 649.47, df = 3, p < 0.00001; I$^2$ = 100%). In addition, triglycerides were measured in 5 (6 intervention groups) post 2000 studies. The MD was -0.25 mmol/L, 95% CI -0.43, -0.08; p = 0.004 (Chi$^2$ = 649.95, df = 5, p < 0.00001; I$^2$ = 99%).
Effect of Exercise Time on Selected Outcome Measures

Table 2 shows changes in outcome measures stratified by weekly exercise time. Overall the response was varied with regard to weekly exercise time.

Study Quality

The TESTEX scale of study quality revealed a median score of 10 (out of a possible 15). Study quality items that were not exhibited by more than 50% of studies were, assessor blinding (0 studies), intention to treat analyses (0 studies), relative exercise intensity review (6 studies) and activity monitoring of the control (non-exercise) groups (0 studies) (See Table 3).

DISCUSSION

Our work is the first to conduct a data pooling analysis of the effects of exercise training and associated moderator variables on clinical markers of type I diabetes control. In children our analyses showed improvements in total daily insulin dose, waist circumference, LDL and triglycerides. In adults there were improvements in body mass, BMI, peak VO$_2$, LDL and triglycerides. Peak VO$_2$ was also improved in studies carried out both pre- and post-2000, whilst LDL and triglycerides decreased in post 2000 studies. There remains insufficient published data to establish the moderating effect of exercise program duration for most of the reported outcome measures, however it is likely that exercise program duration has a moderating role.

Hba1C% did not show a significant change with exercise training. Given that the median duration of included studies was 13 weeks, which is a similar duration to the life of a red
blood cell, it is possible that only partial changes in HbA1c% via exercise training are possible in such a short timeframe. The pre-enrolment physical activity levels of the participants in many of the included studies were unknown, therefore the expected benefit is difficult to ascertain. However, the importance of sustained lifestyle changes to affect health improvements should be reinforced as previous systematic reviews have suggested sedentary behaviour in youths with Type 1 diabetes [28, 29].

Interestingly, exercise led to a significantly reduced body mass in adults, but a significantly increased body mass in children. A similarly increasing effect on body mass with improved hepatic insulin sensitivity has been reported in obese children in response to resistance training [30]. In that study the increased body mass was associated with increased lean body mass [30]. An increase in muscle mass may also explain the weight gain in studies conducted on children in our analysis, particularly since we also showed a decreased waist circumference in the studies conducted on children and a reduced total daily insulin dose. A small, pooled analysis from 2014 suggests equivocal findings with respect to insulin dose [31].

Our serum LDL results showed improvement in both adults and children with exercise. A recent meta-analysis in participants with type 2 diabetes mellitus reported no change in serum LDL [32], whilst an older meta-analysis reporting on apparently healthy elderly participants had results favouring positive changes in LDL [33]. In contrast, a non-randomised controlled trial has shown a reduction in LDL after exercise in children with type 1 diabetes [34].

The change in Peak VO₂ in adults was in the order of 0.8 METs and this moderate effect is to be expected in a known chronic disease group. Our analyses were however unable to identify
that at least 100 minutes of weekly activity is optimal for change in peak VO\textsubscript{2}. Previous work has shown that intensity is the primary stimulus for improved cardiorespiratory fitness in people with cardiac disease [6]. One may expect intuitively that increasing exercise program duration would produce greater improvements in peak VO\textsubscript{2}. It is therefore perhaps surprising that studies comparing shorter and longer exercise program durations have produced non-uniform effects on peak VO\textsubscript{2} [5, 6, 35]. The likely explanation for this phenomenon is that it may be more difficult to get patients to continue to adhere to an exercise program in the longer term.

Our sub-analyses produced conflicting results with respect to weekly exercise time, the more time exercising, the better the effect on glycaemic control, however the less time, the better effect on the lipids. It is remarkable that the exercise guidelines for type II diabetes were one of the first to offer a sliding exercise prescription scale, based upon the manipulation of intensity and weekly duration in order to keep work volume relatively constant [36]. These guidelines suggest 270 weekly minutes of moderate intensity exercise but only 90 minutes of vigorous intensity activity. Our work suggests a varied response to weekly exercise duration, so the existence of a two-tiered exercise prescription could be related to total work, or energy expended. Energy expenditure is the product of exercise duration, intensity and frequency. We were unable to calculate energy expenditure in a sufficient number of the included studies to shed more light on this.

**Limitations**

A major limitation of this work was that considerable heterogeneity meant that data pooling was unjustified in a number of meta-analyses. We systematically attempted to identify reasons for heterogeneity by grouping studies according to similarities in interventions and
exercise programs. We were able to reduce heterogeneity somewhat by limiting data pooling to studies that did not use concurrent dietary interventions. For several of the studies included in this meta-analysis we were unable to determine if medications held steady across the study groups. Even if we knew of medication changes, we would need to assess individual patient data for this to be meaningful. We are therefore unable to gauge the extent to which the observed changes were attributable to any medication changes. A similar issue is true of subjects who exhibited low or high resting heart rate, blood pressure and body mass at group-level, and not patient level, data analysis we are unable to make adjustments to analyses. The exercise training programs varied greatly between studies with respect to exercise intensity, duration, frequency and modality. The normal distribution of the Egger plots evidenced minimal risk of publication bias.

Measures of lean and fat mass would have shed more light onto the role that body composition plays in improving glycaemic control through exercise. We would like to have conducted more moderator variable analyses but limited extracted data precluded this. We were only able to consider program duration, and high/vigorous versus low/moderate exercise intensity sub-analyses.

Conclusions
Exercise training improves some markers of type 1 diabetes severity; particularly body mass, BMI, Peak VO₂ and LDL in adults and insulin dose, waist circumference, LDL and triglycerides in children. Our analysis support existing guidelines that for those who can tolerate it, we were unable to determine if exercise at any intensity offered superior benefits.

Median: 10

Total out of 15 Points

# Three points possible- 1 point if adherence>85%, 1 point if adverse vents reported, 1 point if exercise attendance is reported
*Two points possible- 1 point if primary outcome is reported, 1 point if all other outcomes reported
Highlights

➢ Meta-analysis investigating exercise training in type 1 diabetes

➢ Exercise reduced daily insulin, BMI, peak VO$_2$ and resting heart rate

➢ Exercise also reduced resting systolic blood pressure, LDL and triglycerides

➢ No effect on HbA1C%, Fasting Blood Glucose, body mass or HDL

➢ This could stimulate development of novel treatment regimes for type 1 diabetes
