Abstract

Plankton communities make useful ecosystem indicators, and taking a historical perspective on plankton community composition provides insights into large-scale environmental change. Much of our understanding of long-temporal scale change in plankton communities in the North Sea has been provided by the Continuous Plankton Recorder (CPR) survey, operating since 1931, with consistent time-series data available since 1958. This paper further increases the temporal scale of our understanding of community change in the North Sea by combining the CPR dataset with a digitised collection of plankton surveys undertaken by ICES from 1902 to 1912. After steps taken to integrate the two disparate datasets, differences in overall community composition between time-periods suggest that the multidecadal changes observed through the CPR survey time-period may have occurred from a non-stable baseline that was already on a trajectory of change. Therefore, a stable historical time period in which plankton communities are assessed against for any impact of human pressures may be hard to define for the North Sea and instead underlying variation needs to be encompassed within any baseline chosen. Further evidence for the influence of large scale changes in SST driving change in plankton community composition was found using the extended dataset.

1   Introduction

28

29   Climate change is causing widespread changes in marine ecosystems, superimposed on a background of climate

30   variability that acts at different temporal scales (Hoegh-Guldberg and Bruno, 2010). Plankton communities are

31   sensitive to changes in the physical marine environment, and have been shown to be responsive to interannual and

32   multi-decadal climate variability as well as anthropogenic climate change (Hays et al., 2005). As the base of the

33   pelagic food web, phytoplankton are primary producers (Boyce and Worm, 2015), transferring energy through

34   zooplankton to higher trophic levels (Richardson, 2008). This sensitivity to environmental conditions and their role in

35   the pelagic foodweb makes tracking plankton community change useful as an indicator of change in the wider

36   ecosystem. Much of our understanding of multi-decadal change in plankton communities in the North Sea comes

37   from the Continuous Plankton Recorder (CPR) survey (McQuatters-Gollop et al., 2015). Consistent monitoring data

38   available from 1958 through the present has documented widespread shifts in both phytoplankton and zooplankton

39   communities, specifically the occurrence of basin-scale regime shifts in the North Atlantic (Beaugrand et al., 2014;

40   Reid et al., 2015).

41   The value of plankton time series as evidence for policy and management increases with time. Through using long

42   temporal scale data, the influence of multi-decadal changes in environmental conditions on plankton communities

43   can be investigated, and the most important environmental influences structuring plankton communities on this

44   scale can be identified (Edwards et al., 2010; Giron-Nava et al., 2017). For example, the Atlantic Multidecadal

45   Oscillation is a term for the natural low-frequency SST variability in the North Atlantic that oscillates between warm

46   and cool phases on a ~60yr time scale (Edwards et al., 2013). It has been identified as the second largest

47   macroecological signal in North Atlantic plankton communities, but requires long temporal-scale time-series in order

48   to detect the influence of transitions between oscillatory phases on community change (Edwards et al., 2013).

49   Furthermore, the long temporal scale of the CPR survey can help separate these wider oceanographic and climatic

50   influences on plankton communities, such as the influence of SST, from direct anthropogenic pressures such as

51   eutrophication, which is particularly useful during formal policy assessments (McQuatters-Gollop et al., 2015).

52   'Rescuing' historical ecological datasets, that otherwise may be lost or deemed redundant, has been identified as a

53   useful way of increasing temporal scale in ecological studies, and can be used to address contemporary marine

54 policy challenges, including understanding effects of long-term climate change (Hawkins et al., 2013). Specifically,

55 the use of rescued historical datasets in avoiding 'shifting baselines syndrome' in biodiversity state has received

56 much attention (Pauly, 1995). This is the phenomenon where neglecting historical changes obscures the magnitude

57 of change or variability in ecosystem components. Therefore, rescued historical plankton data can be a tool for

58 avoiding shifting baseline syndrome in our understanding of the multi-decadal dynamics of plankton communities

59 (Ward et al. 2008). The ICES historical plankton dataset used in this study is a dataset of plankton samples collected

60 in the North Atlantic between 1902 and 1912, digitised from historical log books. Hällfors et al. (2013) compared

61 phytoplankton records from this 'rescued' ICES historical dataset in the Baltic Sea with contemporary phytoplankton

62 samples, and documented compositional differences between the two time periods, potentially driven by both

63 climate change and eutrophication. By comparing the ICES historical dataset with North Sea data from the CPR

64 survey, we can better understand changes occurring in North Sea plankton communities pre-1950s, facilitating

65 further exploration of the effects of large scale temperature change to the Continuous Plankton Recorder temporal

66 coverage.

67 Disparities in sampling and analysis methodologies between the ICES historical data and the CPR survey, however,

68 present challenges in their direct comparison, which need to be addressed before using the datasets together.

69 Handling disparate data-types is a key challenge facing regional scale monitoring and assessment where data from

70 multiple different sampling programmes often needs to incorporated (Olli et al., 2013; Zingone et al., 2015). For

71 example, the OSPAR IA2017 regional-scale assessment of plankton communities incorporated multiple time-series

72 from across Europe, where taxa were sampled using different methods, and analysed to differing taxonomic

73 resolutions (OSPAR, 2017). In this study, by integrating and combining the CPR historical time series with the rescued

74 ICES historical dataset, we aim to provide additional contextual information to the changes in North Sea plankton

75 communities between 1958 and 2015 detected by the CPR survey, specifically to address the following questions:

76 • **Is there a difference in plankton community structure (both phytoplankton and zooplankton) between the**

77 **early 20th century and the beginning of the consistently-sampled CPR time period (1960s)?**

78 • **Which plankton communities and individual taxa are most responsive to SST when examining the two**

79 **datasets combined (1902-12, 1958-2015)?**

80

2   Data and Methods

2.1   Data sources

83

2.1.1   Plankton samples

Data from the period 1902-1912 have become available through the ICES historic plankton digitisation project where

13,379 plankton samples have been digitised from seven historical ICES volumes (McQuatters-Gollop et al. 2011).

The data are collated from different sampling programmes, across the North-East Atlantic, North Sea, Irish Sea,

Baltic Sea and Arctic Sea. After digitisation, data tables from the historical volumes were quality checked. The

samples are all spatially referenced and consist of records of taxa at the presence/ absence level or with semi-

quantitative abundance information. In this study, we used all data at the presence/absence level, as to be able to

compare with the Continuous Plankton Recorder survey data. We extracted data from the months February, May,

August and November, as these had the greater numbers of samples. This historical plankton dataset is now freely

available via the ICES data portal (ecosystemdata.ices.dk/HistoricalPlankton/Download.aspx).

The Continuous Plankton Recorder survey has been collecting samples in the North Sea on a routine, consistent basis

since 1958 (Kirby and Beaugrand, 2009). CPRs consist of a filtering mechanism housed in an external body that is

towed behind ships of opportunity at a depth of approximately 6-7m. The speed at which the silk is drawn from a

storage spool is controlled by a propeller, with 10.16 cm of silk corresponding to 18.5 km of tow through the sea

(Batten et al., 2003). CPR data for the months February, May, August and November were obtained for the North

Sea area for phytoplankton (DOI 10.7487/2016.236.1.999) and zooplankton (DOI 10.7487/2016.236.1.998). Although

abundance information is collected for each taxon identified on each sample, for this study data were converted to

presence/absence to make comparable to the ICES historical database.

As well as differences in quantitative resolution between the datasets, there are major structural differences

between the historical ICES surveys and the CPR survey (McQuatters-Gollop et al. 2010). Firstly, the CPR is a

continuous plankton sampling method, using a 270 micron mesh size silk (Richardson et al., 2006).The ICES database,

in contrast, consists of net samples, , collected at fixed point locations by a multitude of disparate sampling cruises

by northern European nations. Therefore, whereas the analysis methodology has remained consistent throughout

107   the CPR series, the composite nature of the ICES dataset means that the sampling and analysis methodologies are

108   not reliably consistent throughout the database. However, both sampling methodologies incorporated sub-sampling,

109   where only a proportion of the sample is analysed, reducing any differences as a result of volume of water filtered

110   (e.g. Hällfors et al. 2012).

111   The mesh sizes of the net samples in the ICES historical database are missing from the sample metadata, and are

112   likely to be varied. The mesh size of the Continuous Plankton Recorder, 270 microns, is larger than the majority of

113   standard plankton nets, which tend to range between 5µm - 80 µm for phytoplankton and 125 µm – 200 µm for

114   zooplankton (John et al., 2001; Castellani and Edwards, 2017) . Importantly therefore, any biases in sampling as a

115   result of mesh size differences between the ICES historical plankton dataset and the CPR data are likely to come

116   from the side of the CPR survey, evidenced by a lower number of species recorded overall than the ICES historical

117   dataset. For example, CPR methodology likely undersamples smaller phytoplankton taxa, although they often are

118   retained on the silk strands of the mesh (taxa as small as 5-10 µm are regularly recorded), which constitutes 30-40%

119   of the mesh area (Batten et al., 2003)Similarly, the CPR survey likely undersamples small zooplankton taxa. A

120   previous study however, comparing CPR data to net samples taken at the L4 sampling station in the Western English

121   channel, that used a mesh size of 200 microns, concluded that although the abundance of zooplankton taxa were

122   generally lower, all dominant zooplankton species recorded at L4 were also common to CPR data (John et al., 2001).

123   In this study, occurrence frequencies of select plankton taxa, based on presence/absence resolution data, were

124   compared between datasets.

125   Samples from both datasets located in the North Sea region were divided into a 'Northern' North Sea region and a

126   'Central/Southern' North Sea region based on the border between ICES regions 4b and 4c (Figure 1). The two spatial

127   areas represent a balance between the need for spatial specificity in comparing plankton communities with known

128   differences occurring across latitudes, and the retention of a reliable sample size within each area. To ensure the

129   depth of the ICES samples were comparable to the CPR dataset all ICES historical samples collected below 15m, or

130   vertical hauls that started below 15m were removed from the resulting sample list, along with samples for which no

131   depth information was given. To compare plankton communities from the same area, CPR samples within half a

132   degree of the ICES historical sample locations were then selected.
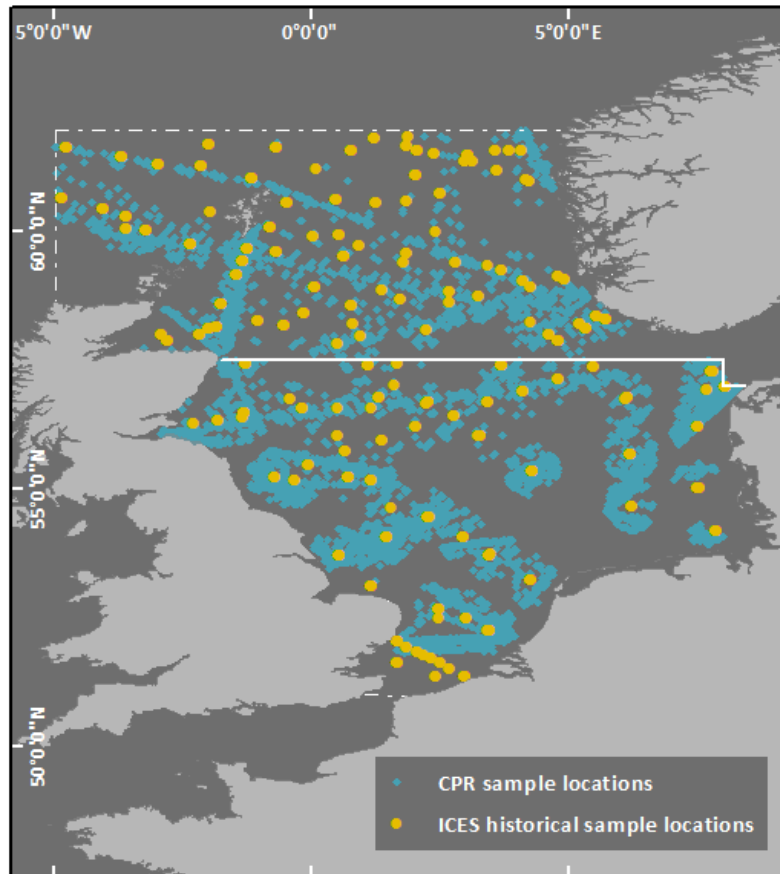

Figure 1. *Location of historical samples (large yellow) and centre points of CPR samples (small blue), included in the study. North Sea area (dashed white line) divided into 'Northern' and 'Central/Southern' areas based on the boundary between ICES subregions 4b and 4c (solid white line).*

2.1.2   Sea surface temperature (SST) data

Monthly SST data were downloaded for the North Sea region from the International Comprehensive Ocean Atmosphere Dataset (ICOADS) at a 2 degree resolution. Data points were extracted from the Northern and Central/Southern North Sea area, and averaged for each year between 1902 and 2015.

2.2   Data preparation

Taxa lists of both phytoplankton and zooplankton were extracted from the historical ICES and CPR databases and both the ICES taxa lists and the CPR taxa lists were run through the Taxon Match Tool available on the WoRMS

155 (World Register of Marine Species) website (http://www.marinespecies.org) to update all names to the most up-to-

156 date accepted nomenclature. Due to the ICES database being a composite of multiple sampling programmes,

157 sporadically occurring taxa were removed, as these may not have been recorded or identified inconsistently

158 between the different sampling programmes. For both datasets, a threshold of 1% frequency of occurrence was

159 selected as a cut-off point for taxa to include in analyses of taxonomic composition. This represented a balance

160 between the need to remove sporadic taxa, as highlighted by Hällfors et al. (2013), but still include rare species in

161 analyses. Because of the decade time-span of the ICES historical dataset, this list for the CPR data was constructed

162 based on a 1% occurrence frequency threshold *in any decade* , to ensure consistency.

163 The taxa lists differed in the taxonomic resolutions of recorded taxa. As the CPR time-period is the longer of the two,

164 and the taxa are generally more coarsely taxonomically resolved, the taxa within the ICES list were aggregated to

165 their equivalent resolution within the CPR taxa list. For example, the CPR taxon name 'Radiozoa' is a phylum,

166 whereas in the ICES taxa list there were four taxon names within the phylum Radiozoa. These taxa were therefore

167 aggregated to the coarser CPR resolution. In some cases, new groups were constructed to aggregate multiple taxa.

168 'Gelatinous zooplankton' was created as Cnidarians and Ctenophores were sometimes recorded as 'Coelenterata'

169 within the ICES dataset. This nomenclature is outdated, and is not a monophyletic group, and so it would be

170 impossible to determine whether these records related to '*Cnidaria*' taxa or '*Ctenophora*' taxa. Some taxa had

171 resolutions too low for aggregation, for example records of '*Crustacea*' with associated life stages 'larvae' or

172 'nauplius'. Samples containing these records were removed before analysis, so the low taxonomic resolution did not

173 skew results. Lastly, taxa that are not consistently recorded throughout the CPR time series, as a result of analysis

174 changes, were removed. Similarly, any taxa within the ICES taxa list that would not be reliably sampled by the CPR

175 due to their small size or delicate nature were removed, thus reducing biases from differing mesh sizes.

176 After integrating the taxonomic nomenclature and resolution of the two taxa lists, of taxa that occurred in over 1%

177 of samples, 39 phytoplankton taxa and 27 zooplankton taxa were unique to the ICES list, whilst 10 phytoplankton

178 taxa and 13 zooplankton taxa were unique to the CPR list. These differences could represent large changes in

179 occurrence frequency over the time period, but could also still be a result of sampling biases between the two

180 datasets, for example though different mesh sizes. We therefore only used taxa that occurred in over 1% of samples

181 in both datasets. These lists of common phytoplankton and zooplankton taxa shared between the two datasets

182   represented taxa that were assumed to be consistently sampled by both surveys (Hällfors et al., 2013), further

183   minimising biases from differing mesh sizes , and consisted of 44 phytoplankton taxa and 30 zooplankton taxa

184   respectively (Table 1). Records of these shared common taxa were then extracted from the CPR and ICES samples,

185   before determining the occurrence frequency of each taxon for each sampling month. Months with fewer than 5

186   samples were removed before analysis.

2.3   Multivariate analysis

To investigate whether significant change occurred in the plankton community between the ICES historical time-period and the beginning of the time-period covered by the CPR survey, we tested for an effect of time period (historical dataset, 1902-1912, to the 1960s decade of the CPR time period) on plankton community composition using multivariate generalised linear models with the '*mvabund*' package in R (Wang et al., 2012). This method fits a generalised linear model to each taxon separately, and then gives a summed likelihood ratio for the given predictors for each model, which can be used as a test statistic ('Sum-of-LR') for the effect of predictors on the community as a whole. Resampling is then done at the whole-sample level (here the sampling month) to test for significance while accounting for correlations between taxa (Wang et al., 2012). The method accounts for a mean-variance relationship in the data (Warton et al., 2012). The generalised linear models were fitted for the occurrence frequency of each taxa in each sampling month, with a complementary log-log link to accommodate the proportional, binomial data (Wang et al., 2012). For each model, the log of the sampling month occurrence frequency total was used as an offset as an approximate method of analysing relative compositional change, and weights were included so that sampling months with higher sample sizes were given stronger weighting. We extracted the univariate statistics for each taxon in the model, to examine the contribution of each taxon to any overall effect.

Furthermore, we visualised change in the plankton community over the extended time period using non-metric Multidimensional Scaling (nMDS) ordination plots. Plots were constructed for each area and plankton type using the vegan package in R (Oksanen et al., 2007). These were constructed based on the relative occurrence frequency of each of the matching list taxa in each sampling month. .

After testing for the effect of time period on community composition, we tested whether SST difference between the two periods could explain any observed differences in community composition using multivariate generalised linear models. Here, models including SST were compared to models including SST and time-period, as a significant effect of time-period over and above SST suggests there is variation between the time-periods not explained by changes in SST alone. Lastly, we tested for any overall effect of SST on plankton community composition, over the whole extended time period, when examining the two datasets combined. Models with SST and season as predictors were compared against models with just season as a predictor to look for the influence over and above seasonality.

3 Results

3.1 Changes in plankton community composition over time

Significant differences in overall community composition were found for both phytoplankton and zooplankton in both the Northern and Central/Southern North Sea areas, suggesting a change in the North Sea plankton community between the beginning of the 20th century and the 1960s. The zooplankton communities showed a stronger overall difference, with larger overall summed likelihood ratios for an effect of time period, despite a lower number of taxa within the list of shared common taxa (Northern North Sea: Sum-of-LR= 1891.3, p= 0.004; Central/Southern North Sea: Sum-of-LR= 2355.5, P=0.003). In contrast, the overall effect of time period, although significant, was lower for phytoplankton communities, suggesting a smaller community change (Northern North Sea: Sum-of-LR= 299.44, p=<0.001; Central/Southern North Sea: Sum-of-LR= 825.65, p<0.001).

However, when extracting the individual contributions of each taxon to the overall community response, a low number of taxa in all communities showed significant contributions to overall community responses. Furthermore, the overall community responses were largely dominated by a low number of taxa. For example, in each community over 20% of the variation was driven by one individual taxon, which showed changes in relative occurrence frequency in all months. These were Protoperidinium (a heterotrophic group) and *Tintinnidae* in the Northern North Sea area for phytoplankton and zooplankton communities respectively, which showed declines. In the Central/Southern North Sea area *Guinardia striata* showed adecline, whilst '*Euphausiacea* and *Mysida'* showed an increase. Out of these taxa, only the decline in *Tintinnidae* in the Northern North Sea was a statistically significant contribution to community change. Other taxa showing large contributions to overall effect were *Dinophysis* within the Northern North Sea phytoplankton community, and *Anomalocera patersoni* within the Northern North Sea zooplankton community, both of which showed a decline ,although the decline in *Dinophysis* was not a statistically significant contribution to community change. Aside from these particular taxa, the overall community change between the beginning of the 20th century and the 1960s was distributed relatively evenly between the taxa, suggesting a holistic community change between the two time periods.

As sampling biases between the datasets, such as varying mesh sizes, may have influenced the taxa that had disproportionate contributions to overall community change, we removed taxa contributing over 20% of variation

244 between time periods before visualising community composition over the extended time period using nMDS plots

245 (Figure 2). 'May 1912' was removed due to being highly anomalous. Here, the stronger effect of time-period on

246 zooplankton composition can be seen with a clearer distinction between the historical (1902-1912) decade and the

247 1960s . Furthermore, there is a clearer distinction between the 1960s and the 2000s within the zooplankton plots,

248 especially for the Central/Southern North Sea, suggesting phytoplankton to be more stable in terms of change in

249 community composition over multi-decadal scales.

250
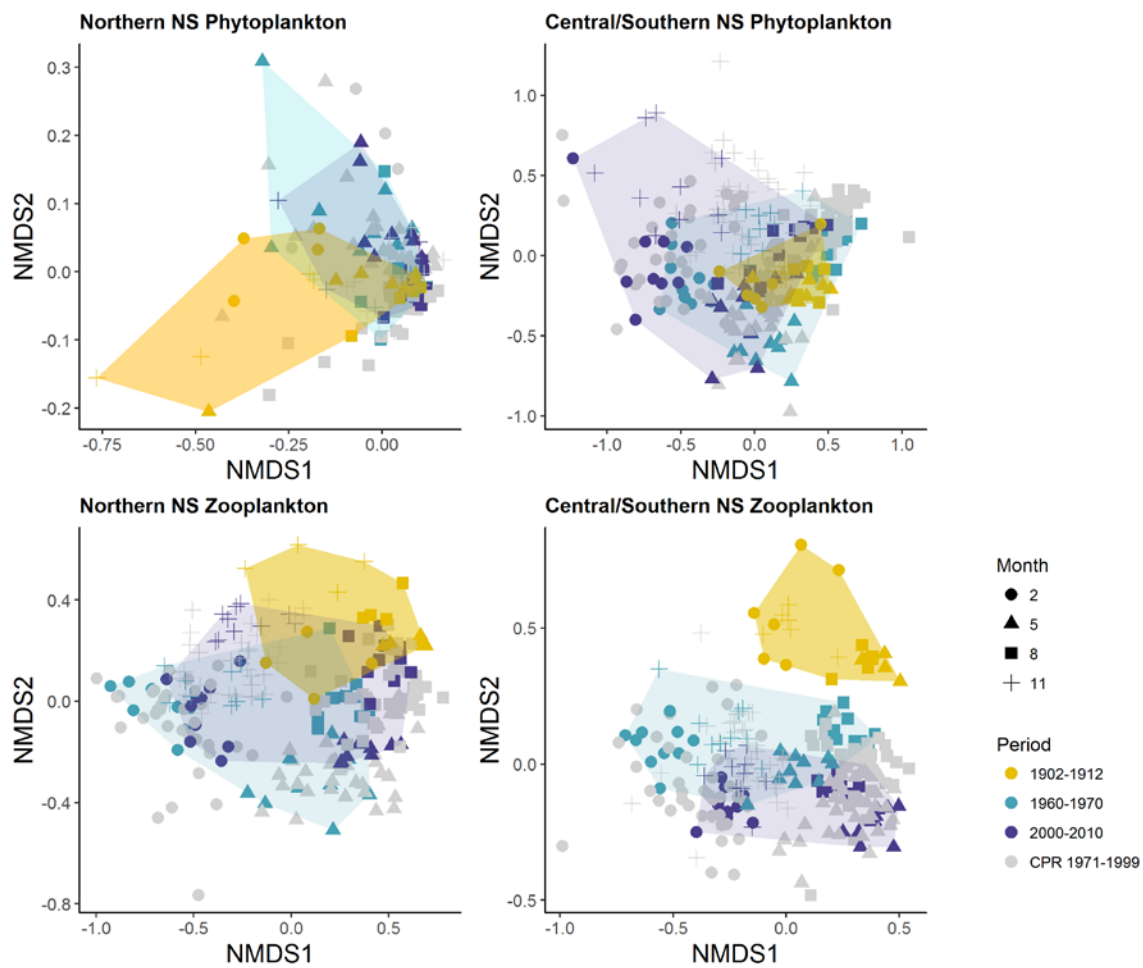

Figure 2. *nMDS plots using Bray Curtis dissimilarity, based on monthly occurrence frequency of the matching list taxa in each North Sea region. Data points from the ICES historical dataset (1902-1912) are shown in orange and are bound by orange polygon (convex hull). K=3 for all except Northern NS zooplankton, where k=4 to lower stress. Data points from 1971-1999 from the CPR survey are shown in grey, with data from the 1960s shown in blue and bounded by blue polygon. Data from the 2000s decade are in purple and bounded by purple polygon, for additional context.*

269

3.2 Influence of SST change on plankton communities

271 Taxa contributing over 20% of between-dataset variation then remained removed when analysing the effect of SST

272 on plankton community composition, to ensure any effects of SST found were not being driven by a small proportion

273 of the taxa. SST has increased in both the Northern and Central/Southern North Sea areasand particularly sharp

274 increases occurred during the late 1920s and 1980s (Figure 3). The average annual SST for the ICES historical time

275 period (1902-1912) was 9.00 °C for the Northern North Sea area, rising to 9.53 °C in the 1960s. In the

276 Central/Southern North Sea area, the average SST for the ICES historical time period was 9.59 °C, rising to 9.86 °C in

277 the 1960s.

278
286 *Figure 3. North Sea SST variation between 1902 and 2015. Annual data are in grey and the 5 year mean is in blue.*

287

288 Differences in SST between the time periods suggest that changes observed in overall plankton community

289 composition between 1902-1912 and the 1960s coincided with changes in environmental conditions within the

290 North Sea. We tested this further using multivariate generalised linear models; a significant effect of time-period

291   over and above SST suggests there is variation between the time-periods not explained by changes in SST alone. A

292   significant effect of time period over and above SST was found only in the Central/Southern North Sea

293   phytoplankton community (p=0.023), suggesting variation between time-periods could not be explained by SST

294   change only in this community. In the Northern North Sea zooplankton and phytoplankton communities, as well as

295   the Central/Southern zooplankton community there was no significant effect, suggesting variation could be linked to

296   large-scale SST change.

297

298   When then using both the ICES historical dataset and the full CPR dataset together, giving an extended temporal

299   coverage, we found significant effects of SST on phytoplankton and zooplankton communities in both the Northern

300   and Central/Southern North Sea areas (Table 2). SST had a greater influence in the Central/Southern North Sea than

301   the Northern North Sea area on both phytoplankton and zooplankton composition, and a larger influence on

302   zooplankton than phytoplankton overall. No phytoplankton taxa showed individual significant contribution to overall

303   community response. In contrast, there were multiple individual significant contributions to the overall response

304   within zooplankton communities, with the most number of significant individual contributions shown in the

305   Central/Southern North Sea. These included both meroplankton and holoplankton taxa, with the largest

306   contributions to overall community response from *Centropages typicus* and the multi-species group *Bivalvia*.

307   *Centropages typicus* showed an increase in relative occurrence frequency over time, whilst *Bivalvia* showed a

308   decrease in relative occurrence frequency over time, coinciding with increasing annual SST (Figure 4).

309

328 Although overall community composition change between 1902-1912 and the 1960s may be linked to changes in

329 SST, taxa that had the largest univariate contributions to community change did not necessarily have large responses

330 to SST across the wider time period (1902-1912, 1958-2015). This suggests that although a change in temperature

331 conditions may have contributed to the overall community response, it does not necessarily explain individual taxon

332 changes between the two time periods. Furthermore, any potential influences of specific environmental drivers on

333 community composition differences between the two time-periods may be at least partially obscured by the

334 differences in sampling and analysis methodologies between the two datasets used, and the low quantitative

335 resolution available.

336

337 **4   Discussion**

338 Here, we have demonstrated the value of 'rescued' historical plankton data in increasing the temporal scale of

339 understanding of community change. By harmonising the taxonomic lists from the two datasets in order to ensure

340 comparability and then further selecting a subset of shared, common taxa based on a 1% occurrence frequency

341 threshold, and using presence/absence semi-quantitative resolution, we have reduced the influence of disparate

342 sampling and analysis methodologies. Results suggest that the 1960s had a significantly different plankton

343 community composition compared to the early 1900s, indicated by variation in the relative occurrence frequency of

344 shared common taxa. Differences in community composition between time periods were largely driven by a small

345 number of taxa. The remaining effect was shared relatively evenly between the remaining taxa, suggesting the

346 overall significant changes in community composition are a result of subtle change across the taxa list, with

347 individual taxa having mainly non-significant contributions to overall community response.

348 Zooplankton communities showed a greater difference between the ICES historical time period and the 1960s

349 decade of the CPR time period than phytoplankton communities. The nMDS plots also revealed clearer visual

350 distinctions between the 1960s decade and the 2000s decade within the zooplankton communities than within the

351 phytoplankton communities. This suggests that although differences between the time periods were found within

352 phytoplankton communities, over the whole time period the phytoplankton community showed less directional

353 change in community composition at the multi-decadal scale than zooplankton communities. A similar result was

354 found during the OSPAR (Oslo-Paris Convention for the Protection of the North-East Atlantic) Intermediate

355 Assessment 2017, where larger changes in indicators of zooplankton community structure were found compared to

356 phytoplankton communities (OSPAR, 2017). This assessment result could therefore be representative of multi-

357 decadal patterns of variation occurring at the century-scale.

358 Furthermore, we found that the plankton community change identified between 1902-1912 and the 1960s could be

359 explained through changes in SST in Central/Southern North Sea zooplankton and Northern North Sea

360 phytoplankton and zooplankton. These community changes in response to SST could therefore be attributed to a

361 regime shift that has been shown to have occurred in the North Atlantic during the 1920s and 1930s, which is argued

362 to be the largest and most significant climate-induced regime shift of the 20th century (Drinkwater, 2006), associated

363 with increases in SST. Furthermore, change in the Central/Southern North Sea phytoplankton community could not

364 be explained by SST change. It is likely, therefore, that finer scale changes, in variables other than SST, drove the

365 change in the Central/Southern North Sea phytoplankton community. Hällfors et al. (2013) similarly described an

366 unknown 'period effect' between the ICES historical time period and contemporary phytoplankton samples in the

367 Baltic Sea, where variation could not be explained by environmental change alone, and instead they hypothesise a

368 potential signal of eutrophication in the change observed. At the regional scale in the North Sea however, previous

369 research has suggested that eutrophication occurs mainly in coastal regions, rather than open sea (McQuatters-

370 Gollop et al., 2009). Furthermore, although we are confident that differences in taxonomic nomenclature and

371 resolution are not driving any patterns observed, we cannot rule out an influence of the low quantitative resolution

372 resulting from sampling and analysis biases, especially for the taxa showing disproportionate contributions to the

373 overall community response.

374 By integrating the CPR survey with the ICES historical data, we facilitated exploration of the influence of warming

375 SSTs on multidecadal plankton community change at the century-scale, although focusing on occurrence frequency,

376 rather than abundance values. Over the extended time period (1902-1912, 1958-2015), SST had a stronger influence

377 on zooplankton communities than phytoplankton, in both the Northern and Central/Southern North Sea areas. In

378 particular, it is known that temperature is an important structural variable for zooplankton communities and is a key

379 determinant of the limits to distributions (Richardson, 2008). In contrast, although SST was a significant driver of

380 community composition in phytoplankton in both the Northern and Central/Southern North Sea, no single taxa

381 showed significant contributions to the overall community effect. Previous studies have suggested the importance of

382 physical variables other than SST directly influencing phytoplankton community composition including salinity and

383 wind stress (Hinder et al., 2012).

384 Multiple zooplankton taxa in the Central/Southern North Sea area showed significant univariate responses to SST

385 change, with *Centropages typicus* and the multi-species group *Bivalvia* showing the largest responses. A positive

386 association between the abundance of *Centropages typicus* and SST has previously been identified in the North Sea

387 (Lindley and Reid, 2002), and this pattern is also shown here when examining the CPR time-series at a

388 presence/absence resolution. The lack of a large difference in relative occurrence frequency between the beginning

389 of the 20th century and the 1960s found here however suggests that the response of *Centropages typicus* to SST

390 occurred since the 1960s. In contrast, the larger difference in the occurrence frequency of *Bivalvia* found here

391 between the beginning of the 20th century and the 1960s suggests the decline in the abundance of bivalve larvae

392 previously identified in the North Sea (Kirby et al., 2008) occurred over a longer time scale. Kirby et al. hypothesise

393 that the long-term decline in bivalve larvae found through the CPR survey is a result of predation from increasing

394 abundance of decapod larvae, also observed through the CPR survey, and the increase in decapod larvae is

395 associated with increasing SST (Lindley et al., 2010). In this study, decapod larvae in the Central/Southern North Sea

396 had a significant response to SST, and increased in relative occurrence between 1902-1912 and the 1960s,

397 suggesting that trophic amplification of a climate signal could explain the decrease in bivalve larvae also at the

398 century scale. The differences in whether the taxa with strong overall responses to SST also showed large differences

399 in occurrence frequency between time periods suggests that the temporal scale of responses to SST change, and

400 temporal scale of baseline shifts, is variable between individual taxa.

401

402 **4.1   Conclusions and policy implications**

403 Through integrating and directly comparing the CPR dataset to the ICES historical database, important

404 considerations have been identified for using disparate plankton datasets together, with applications for large scale

405 assessment and integrated monitoring programmes, such as regional scale assessments undertaken at the OSPAR

406 level (OSPAR 2017). Particularly, zooplankton taxa varied greatly in the taxonomic resolution in which they were

407 recorded between surveys, and much attention needs to be drawn to this when designing integrated monitoring

408 programmes constructed from different surveys. However, we have shown that a subset list of shared common taxa

409 can inform on community change when combining data from disparate sources. Furthermore, occurrence frequency

410 seems to be a relevant proxy for abundance, when abundance data is non-comparable, for example occurrence

411 frequency resolution still revealed strong seasonality signals. As sampling and analysis biases cannot ever be fully

412 reconciled in contemporary comparisons of rescued historical datasets, such as varying mesh sizes, often resulting in

413 low quantitative resolution, we suggest that 'rescued' historical datasets can be useful as an additional contextual

414 tool for understanding climate change effects on plankton communities, but caution should be employed when

415 using disparate historical datasets as robust evidence bases on their own.

416 A stable historical baseline, from which plankton communities are assessed for impacts of direct anthropogenic

417 pressures, may be hard to define in the North Sea, as the plankton communities vary on inter-annual, multi-decadal

418 and, suggested here, century-wide scales in response to environmental change. Phytoplankton community

419 composition may show less directional change in community composition, in terms of the relative occurrence

420 frequency of common taxa, over multi decadal time scales than zooplankton communities. Although statistically

421 significant changes were observed in particular individual taxa between time periods, and across the wider time-

422 series in response to SST, this does not necessarily inform on the ecological significance of changes. When formally

423 assessing change in North Sea plankton communities under policy drivers, it is important to consider the functional

424 consequences of community change, as well as the century-scale shifts in community composition baselines.
