Abstract

The beetle superfamily Dytiscoidea, placed within the suborder Adephaga, comprises six families. The phylogenetic relationships of these families, whose species are aquatic, remain highly contentious. In particular the monophyly of the geographically disjunct Aspidytidae (China and South Africa) remains unclear. Here we use a phylogenomic approach to demonstrate that Aspidytidae are indeed monophyletic, as we inferred this phylogenetic relationship from analyzing nucleotide sequence data filtered for compositional heterogeneity and from analyzing amino-acid sequence data. Our analyses suggest that Aspidytidae are the sister group of Amphizoidae, although the support for this relationship is not unequivocal. A sister group relationship of Hygrobiidae to a clade comprising Amphizoidae, Aspidytidae, and Dytiscidae is supported by analyses in which model assumptions are violated the least. In general, we find that both concatenation and the applied coalescent method are sensitive to the effect of among-species compositional heterogeneity. Four-cluster likelihood-mapping suggests that despite the substantial size of the dataset and the use of advanced analytical methods, statistical support is weak for the inferred phylogenetic placement of Hygrobiidae. These results indicate that other kinds of data (e.g. genomic meta-characters) are possibly required to resolve the above-specified persisting phylogenetic uncertainties. Our study illustrates various data-driven confounding effects in phylogenetic reconstructions and highlights the need for careful monitoring of model violations prior to phylogenomic analysis.

Keywords: Hydradephaga, Aspidytidae, transcriptomics, RNA-seq, compositional bias.

77 **1. Introduction**

78 Almost half of the ca. 13,000 beetle species with an aquatic lifestyle (Jäch and Balke, 2008)
79 belong to the suborder Adephaga, which also contains more than 38,000 species of the terrestrial
80 Carabidae and Trachypachidae. The aquatic (or semi-aquatic) adephagan families Amphizoidae,
81 Dytiscidae, Gyrinidae, Haliplidae, Hygrobiidae, and Noteridae have traditionally been considered
82 as monophyletic and collectively referred to as "Hydradephaga" (Crowson, 1960). The monophyly
83 of "Hydradephaga" has not been corroborated in extensive phylogenetic analyses of morphological
84 data or in recent phylogenomic investigations (e.g. Baca et al., 2017; Beutel, 1993; Beutel et al.,
85 2008, 2006; Beutel and Haas, 1996; Beutel and Roughley, 1988; Dressler et al., 2011; Dressler and
86 Beutel, 2010; S. Zhang et al., 2018; but see López-López and Vogler, 2017). On the other hand, the
87 monophyly of the superfamily Dytiscoidea (Amphizoidae, Aspidytidae, Dytiscidae, Hygrobiidae,
88 Meruidae, and Noteridae) is well established (e.g. Baca et al., 2017; Beutel et al., 2013; Dressler et
89 al., 2011; but see López-López and Vogler, 2017). Species of this superfamily can be encountered
90 in virtually every kind of freshwater habitat, including springs, rivers, acidic swamps, lakes, and
91 even in hypersaline or hygropetric habitats. Their widespread occurrence is primarily due to the
92 astounding ecological versatility of species in the family Dytiscidae (Miller and Bergsten, 2016).
93 Interestingly, the phylogenetic relationships within Dytiscoidea are still obscure, especially
94 concerning the hypothesized monophyly of Aspidytidae and the phylogenetic affinities of its
95 species to those of the families Amphizoidae and Hygrobiidae. In the present phylogenomic study,
96 we investigate the above-outlined phylogenetic questions with the largest molecular dataset
97 compiled to date for studying phylogenetic relationships in this group of beetles.

98 Most species of Dytiscoidea are strictly aquatic, but two families with species inhabiting
99 hygropetric habitats have recently been described. The species of these families occur in
100 geographically disjunct regions. Meruidae, with the single species *Meru phyllisae* Spangler and
101 Steiner, 2005, is known only from the Guiana Shield region of Venezuela (Spangler and Steiner,

102 2005). Aspidytidae contain two species, *Sinaspidytes wrasei* (Balke, Ribera, Beutel, 2003) from
103 China (Balke et al., 2003; Toussaint et al., 2015) and *Aspidytes niobe* Ribera, Beutel, Balke, Vogler,
104 2002 from the Cape region of South Africa (Beutel et al., 2010; Ribera et al., 2002a). Phylogenetic
105 analyses have placed these two families in the superfamily Dytiscoidea (Beutel et al., 2006; Ribera
106 et al., 2002a), along with the Dytiscidae (diving beetles, 4,489 species; Nilsson and Hájek, 2019),
107 Noteridae (burrowing water beetles, 258 species; Nilsson, 2011), Hygrobiidae (squeak beetles, six
108 species) and Amphizoidae (trout stream beetles, five species). The taxonomy of Dytiscoidea has
109 been extensively studied, as have been its morphological and ecological adaptations (Balke and
110 Hendrich, 2016; Miller and Bergsten, 2016) and the anatomy of adults and larvae (Belkaceme,
111 1991; Beutel, 1993, 1988, 1986a, 1986b; Dressler and Beutel, 2010). Moreover, species of the
112 group are well documented in the fossil record and can be traced back to the Triassic (e.g. Beutel et
113 al., 2013; Ponomarenko, 1993).

114 The phylogenetic relationships of dytiscoid beetles have been addressed in numerous studies
115 investigating morphology, chemical gland compounds, fossil data, and DNA sequences (Alarie et
116 al., 2011, 2004; Alarie and Bilton, 2005; Baca et al., 2017; Balke et al., 2008, 2005; Beutel et al.,
117 2006; Beutel, 1993; Beutel et al., 2013, 2008; Beutel and Haas, 1996; Burmeister, 1976; Dettner,
118 1985; Kavanaugh, 1986; López-López and Vogler, 2017; McKenna et al., 2015; Ribera et al.,
119 2002b; Toussaint et al., 2015). Analyses of these different data have not yielded congruent
120 topologies (see Fig. 1 for selected hypotheses). The currently accepted view is that Meruidae +
121 Noteridae represent the sister clade of the remaining four families of the superfamily Dytiscoidea
122 (Fig. 1). However, the affinities of Amphizoidae, Aspidytidae, Dytiscidae, and Hygrobiidae remain
123 unresolved. A clade consisting of Dytiscidae and Hygrobiidae is supported by some morphological
124 features (Balke et al., 2005; Beutel et al., 2006; Dressler and Beutel, 2010), such as the presence of
125 prothoracic glands (Beutel, 1988, 1986b; Forsyth, 1970) but molecular and total evidence analyses

126 have yielded incongruent topologies (e.g. Baca et al., 2017; Balke et al., 2005; Ribera et al., 2002a;
127 Toussaint et al., 2015).

128 A sister group relationship between Amphizoidae and Aspidytidae has been suggested in
129 previous studies analyzing molecular data (Balke et al., 2008, 2005; Hawlitschek et al., 2012;
130 Toussaint et al., 2015), but Toussaint et al. (2015) recovered paraphyletic Aspidytidae (in relation to
131 Amphizoidae). Specifically, in a multigene analysis of nucleotide sequence data, and after
132 excluding the highly saturated third codon positions, *A. niobe* was placed as a sister taxon of
133 Amphizoidae (Fig. 1f). This new hypothesis contributed to the existing confusion on character
134 evolution within Dytiscoidea (Balke et al., 2005; Beutel et al., 2006; Ribera et al., 2002a), because
135 morphological characters of the adult beetles (antenna: configuration of scape and pedicel) suggest
136 a monophyletic Aspidytidae, while morphological characters of the larvae of *S. wrasei* show
137 considerable structural affinities with those of Amphizoidae (Toussaint et al., 2015).

138 Given the above outlined uncertainties in the phylogenetic relationships of the families
139 currently included in Dytiscoidea we 1) investigated whether Aspidytidae are monophyletic and 2)
140 inferred the phylogenetic relationships among the families Amphizoidae, Aspidytidae, Dytiscidae,
141 Hygrobiidae, and Noteridae based on an extensive transcriptomic dataset. In order to achieve these
142 goals, we analyzed whole body transcriptomes of species of all major lineages of Dytiscoidea
143 except Meruidae. We also investigated the effects of different potential sources of conflicting
144 phylogenetic signal and phylogenomic incongruence when estimating phylogenetic relationships
145 within Dytiscoidea, and evaluated the degree of confidence for alternative topologies using branch
146 support tests and a data permutation approach.

147

148

149

150

151 **2. Materials and methods**

152 **2.1 Taxon sampling**

153 We compiled a dataset consisting of *de novo*-sequenced transcriptomes and of previously 154 published transcriptomes of Dytiscoidea (Table 1). The sampled species represent all extant 155 families of Dytiscoidea except Meruidae (for which transcriptomic data were not available). As 156 there is high confidence in the hypothesized sister group relationship between Meruidae and 157 Noteridae (Baca et al., 2017; Balke et al., 2008; Beutel et al., 2006; Dressler et al., 2011; Toussaint 158 et al., 2015), we do not deem the lack of the species *M. phyllisae* from our dataset as problematic 159 for investigating the major relationships of Dytiscoidea (see Fig. 1). Representatives of Gyrinidae 160 and Haliplidae were included as outgroups (Baca et al., 2017; Beutel et al., 2013, 2006; Beutel and 161 Haas, 1996; Beutel and Roughley, 1988; Dressler et al., 2011; Dressler and Beutel, 2010).

162 The *de novo*-sequenced and assembled transcriptomes were screened for putative adaptor, 163 vector and cross-contaminated sequences (see Suppl. Text 1), and clean assemblies were 164 subsequently submitted to the NCBI-TSA database (Table 1). For a detailed description of the 165 procedures for specimen collection and preservation, RNA isolation, RNA library preparation, 166 transcriptome sequencing, transcriptome assembly, cross-contamination screening and sequence 167 submissions see the Supplementary Text 1. We used custom made Perl and Python scripts to 168 calculate descriptive statistics for each transcriptome in our study (Table 1).

169

170 **2.2 Orthology assignment and alignment refinement**

171 We identified 3,085 clusters of single-copy genes (COGs) that are non-homologous or out-172 paralogous among each other at the hierarchical level Endopterygota, based on a customized profile 173 query in OrthoDB v.9.1 (Zdobnov et al., 2017) (see Suppl. Text 1). Our query was based on six 174 endopterygote species (subsequently referred to as reference species) with well sequenced and 175 annotated genomes (Suppl. Table 1). Each transcriptome was searched for transcripts orthologous

176 to the sequences of a given COG (see Peters et al., 2017; Petersen et al., 2017). This search was
177 performed with Orthograph v.0.6.1 (Petersen et al., 2017). Orthologous sequences for each COG
178 (including those of the reference species) were combined in two FASTA files: one containing
179 sequences at the transcriptional level (i.e. nucleotides, nCOGs), the other containing sequences at
180 the translational level (i.e. amino acids, aaCOGs). The resulting nCOGs and aaCOGs are deposited
181 at MENDELEY DATA (XXXXX).

182 Alignment of the amino-acid sequences in each aaCOG, was performed with MAFFT v.7.309
183 (Katoh and Standley, 2013) using the algorithm L-INS-i. We screened the amino-acid multiple
184 sequence alignments (MSAs) for potentially misaligned sequences and erroneously identified
185 orthologs using the procedure outlined by Misof et al. (2014). We also adapted the alignment
186 refinement procedure proposed by Misof et al. (2014). Amino-acid and nucleotide sequences that
187 were still identified as outliers after the alignment refinement procedure were removed from the
188 MSAs.

189 Following the alignment refinement procedure, we removed all sequences of the reference
190 species from the aligned aaCOGs and also discarded their corresponding nucleotide sequences. This
191 resulted in FASTA files that comprised exclusively (aligned) amino-acid or (unaligned) nucleotide
192 sequences of Dytiscoidea and of the outgroup families Gyrinidae and Haliplidae. Next, we
193 discarded all COGs from the ortholog set containing transcripts from fewer than three species. After
194 removing gap-only and ambiguous-only positions from the remaining 2,991 aaCOGs we generated
195 codon-based nucleotide sequence alignments, with a modified version of the script Pal2nal.pl
196 (Suyama et al., 2006) as described by Misof et al. (2014). The 2,991 aligned aaCOGs and the
197 corresponding codon-based alignments are deposited at MENDELEY DATA (XXXXX).

198

199

200

201 **2.3 Concatenation-based and gene-tree-based analysis of amino-acid sequence data**

202 We generated eleven amino-acid supermatrices (Table 2, Suppl. Fig. 1) and assessed the effects
203 of different putative sources of topological incongruence on our concatenation-based phylogenetic
204 inference, namely: 1) alignment masking (i.e. alignment column-filtering) of individual gene
205 partitions when analyzed in a supermatrix context 2) effects of data coverage and phylogenetic
206 information content on the dytiscoid phylogenetic relationships 3) taxonomic decisiveness of gene
207 partitions with respect to a specific phylogenetic question, and 4) effects of compositionally
208 heterogeneous genes in a supermatrix context. We modified the initial supermatrix (supermatrix A,
209 Table 2) by masking the effects of each of the above-mentioned factors one by one (e.g. by
210 removing the randomly similar sections in each gene or removing partitions with low information
211 content). This hierarchical masking strategy progressively resulted in supermatrices to be analyzed
212 with fewer genes and fewer amino-acid alignment sites. We used each generated dataset (Table 2,
213 Suppl. Fig. 1) to infer the phylogeny of Dytiscoidea. The purpose of these analyses was to assess
214 whether or not gradual masking of the initial supermatrix for any of the above factors affected the
215 results of the phylogenetic inference. Amino-acid supermatrices A–K are deposited at MENDELEY
216 DATA (XXXXX).

217

218 **2.3.1 Masking of the individual amino-acid MSAs**

219 It has been suggested that current methods of alignment masking may lead to biased
220 phylogenetic inferences because alignment columns are filtered too aggressively (Tan et al., 2015).
221 To assess the effect of alignment masking on our results, we first concatenated the original MSAs
222 of aaCOGs without applying alignment masking (supermatrix A). We then applied ALISCORE
223 v.1.2 (Kück et al., 2010; Misof and Misof, 2009) on each aaCOG separately with the options: -r
224 10^{27} (for the maximum number of pairwise sequence comparisons) and -e. The masked genes
225 (aaCOGs) were then concatenated in a new masked supermatrix (supermatrix B). Concatenation of

226 both masked and unmasked amino-acid MSAs was conducted with FASconCAT-G v.1.02 (Kück
227 and Longo, 2014).
228

229 **2.3.2 Increasing data coverage and phylogenetic information content**

230 We evaluated whether or not increasing the saturation (SV, the overall degree of data coverage
231 with respect to gene presence or absence) and the phylogenetic information content (IC) of the
232 supermatrix, as a function of data coverage and phylogenetic signal, had an effect on our tree
233 reconstructions. IC and SV values were calculated with MARE v.0.1.2-rc (MAtrix REduction)
234 (Misof et al., 2013). We generated and assessed the following amino-acid supermatrices:

235 1) supermatrix C: selected optimal subset (SOS, default output supermatrix) of the software
236 MARE when using supermatrix B as input;

237 2) supermatrix D: inferred from supermatrix B after removing those genes with IC = 0;

238 3) supermatrix E: selected optimal subset (SOS, default output supermatrix) of the software
239 MARE when using supermatrix D as input.

240 We also calculated the SV and the IC of every other amino-acid supermatrix (Table 2). In
241 addition, we calculated the overall alignment completeness scores (C_a) for all supermatrices
242 (Tables 2 and 3) with AliStat v.1.6 (https://github.com/thomaskf/AliStat, see Misof et al., 2014).
243 The overall completeness score provides a direct measure of the overall degree of missing data in
244 each analyzed supermatrix. Moreover, we generated heatmaps of pairwise completeness scores for
245 every amino-acid and nucleotide sequence supermatrix that we analyzed (Suppl. Fig. 3–23).
246

247 **2.3.3 Controlling for data decisiveness**

248 We constructed two amino-acid sequence supermatrices to control for data decisiveness
249 following the approach outlined by Dell'Ampio et al. (2014). Data decisiveness refers to the
250 property of a partition to include data of every group of species that is relevant to address a specific

251 phylogenetic question (e.g. the monophyly of Aspidytidae). We generated a subset of supermatrix E
252 by including only those aaCOGs in which all 14 species were present (supermatrix F). An
253 additional decisive dataset (supermatrix G) was constructed by including only those aaCOGs that
254 included at least one representative of Amphizoidae, Dytiscidae, Gyrinidae, Haliplidae,
255 Hygrobiidae, Noteridae, and both representatives of Aspidytidae (*A. niobe* + *S. wrasei*). These two
256 amino-acid sequence datasets were considered decisive for addressing the inter-familiar
257 relationships of Dytiscoidea and the monophyly of Aspidytidae.
258

259 **2.3.4 Controlling for among-species compositional heterogeneity**

260 Compositional heterogeneity among species in a dataset is often neglected as a source of
261 systematic error in molecular phylogenetic studies (Jermiin et al., 2004; Nesnidal et al., 2010;
262 Philippe and Roure, 2011; Romiguier et al., 2016; Whitfield and Kjer, 2008). We explicitly
263 explored whether among-species compositional heterogeneity biased tree reconstructions.
264 Compositionally heterogeneous aaCOGs were excluded from the decisive amino-acid dataset
265 (supermatrix F) to generate a decisive and more compositionally homogeneous matrix (supermatrix
266 H, Suppl. Fig. 1). Among-species compositional heterogeneity was assessed for each partition
267 separately, based on the partition-specific relative composition frequency variation value (RCFV)
268 (Zhong et al., 2011) calculated by BaCoCa v.1.105 (Kück and Struck, 2014). We followed
269 Fernandez et al. (2016) by considering compositional heterogeneity among species in a given
270 aaCOG to be high when the overall RCFV value was greater than or equal to 0.1. We also filtered
271 supermatrix A and supermatrix E using the same threshold (Table 3, supermatrices J and K) and
272 compared results of tree reconstructions. Complementary to the RCFV approach, we used the
273 software SymTest v.2.0.47 (https://github.com/ottmi/symtest) to calculate the overall deviation
274 from stationarity, reversibility, and homogeneity (SRH) (Jermiin et al., 2008) between the amino-
275 acid (or nucleotide) sequences of the species in each generated supermatrix (see Misof et al., 2014

276 and Suppl. Text 1). We generated heatmaps to visualize the pairwise deviations from SRH
277 conditions in each generated supermatrix in our study (Suppl. Text 1, Suppl. Fig. 24–44).
278
279 **2.3.5 Maximum likelihood phylogenetic analyses of amino-acid sequence data**
280 For each of the amino-acid sequence supermatrices (A–K) ten independent partitioned tree
281 searches were performed using IQ-TREE v.1.5.5 (or later) (Nguyen et al., 2015) by specifying the
282 aligned aaCOG boundaries. Model selection for each aaCOG was performed with ModelFinder
283 (Kalyaanamoorthy et al., 2017), implemented in IQ-TREE. We considered the following amino-
284 acid substitution models: DAYHOFF (Dayhoff et al., 1978), DCMUT (Kosiol and Goldman, 2005),
285 JTT (Jones et al., 1992), JTTDCMUT (Kosiol and Goldman, 2005), LG (Le and Gascuel, 2008),
286 LG4X (Le et al., 2012), and WAG (Whelan and Goldman, 2001) allowing all possible
287 combinations of modeling rate heterogeneity among sites (options: -mrate E,I,G,I+G,R -gmedian -
288 merit AICc). We used the edge-linked partitioned model for tree reconstruction (option: -spp)
289 allowing each gene to have its own rate but assuming a common topology and proportional branch
290 lengths among all gene partitions (Chernomor et al., 2016). For each supermatrix the most
291 appropriate model for each gene partition was selected during the first tree search (option -m MFP).
292 The resulting NEXUS files of the first run were used as input for all remaining tree searches.
293 A common practice in phylogenomic analyses is to optimize the partitioning schemes and
294 corresponding substitution models for the data within an algorithmic framework (Lanfear et al.,
295 2014, 2012). Such optimizations of the partitioning schemes are time-consuming and could result in
296 combining different genes in different meta-partition analyses due to the heuristic optimization
297 procedures implemented in the existing software (Lanfear et al., 2014). This can lead to very
298 different model assignments for different genes and therefore would add an additional
299 uncontrollable effect when comparing different supermatrices. By defining the original masked
300 gene boundaries for all supermatrices and by not optimizing the partitioning schemes we excluded

301 the effects of differential model fit (due to the different composition of the inferred meta-partitions
302 in each matrix) on the results of tree reconstructions. However, in order to avoid missing a unique
303 topology of Dytiscoidea due to suboptimal model fit we optimized the partitioning scheme for a
304 selection of amino-acid supermatrices. We selected the supermatrices H and E for this purpose,
305 because they gave rise to different topologies when analyzing amino-acid sequence data. We used
306 the relaxed clustering algorithm (rcluster) (Lanfear et al., 2014) and RaxML v.8.2 (options: -raxml -
307 rcluster-max 5000) (Stamatakis, 2014) in PartitionFinder v.2.1.1 (Lanfear et al., 2017) to merge
308 partitions according to the default weights under the AICc information criterion. We restricted the
309 model search in PartitionFinder to the following amino-acid substitution models: DAYHOFF+G,
310 DAYHOFF+G+F, DCMUT+G, DCMUT+G+F, JTT+G, JTT+G+F, LG+G, LG+G+F, LG4X,
311 WAG+G, and WAG+G+F. The inferred schemes and models for the corresponding meta-partitions
312 were defined as input for the IQ-TREE tree searches (v.1.5.5) again with the edge-linked model.
313 Ten independent tree searches were performed with the optimized partitioning schemes of
314 supermatrix E and H. The resulting NEXUS files with the optimized schemes of supermatrix E and
315 of supermatrix H are deposited at MENDELEY DATA (XXXXX). Statistical support of our
316 inferred relationships was assessed based on the non-parametric bootstrap measure (Felsenstein,
317 1985) and the bootstrap by transfer (TBE) support measure (Lemoine et al., 2018). We calculated
318 100 non-parametric bootstrap replicates and TBE support using the unoptimized partitioning
319 schemes of all the analyzed amino-acid datasets (Table 2). In addition, we calculated 100 non-
320 parametric bootstrap replicates and TBE support for the optimized partitioning schemes of
321 supermatrices E and H. Subsequently, we mapped the bootstrap support values on the maximum
322 likelihood trees (i.e. trees with the best log-likelihood among all ten tree searches).

323 For the optimized partitioning schemes of the supermatrices E and supermatrix H we also
324 performed one additional tree search with the options -bb 1,000 -alrt 10,000 -abayes to estimate
325 different measures of branch support implemented in IQ-TREE v.1.5.5: Ultrafast Bootstrap 1

326 (UFBoot1), SH-like aLRT, and aBayes respectively (Anisimova et al., 2011; Guindon et al., 2010;
327 Minh et al., 2013). We also separately calculated branch support based on the updated version of
328 Ultrafast Bootstrap in IQ-TREE v.1.6.8 (UFBoot2, option: -bnni) with 1,000 replicates (Hoang et
329 al., 2017). After verifying topological congruence to the maximum likelihood tree, we mapped the
330 different branch support values on the maximum likelihood tree (Fig. 2).

331 For a selection of amino-acid supermatrices, we performed one additional tree search using IQ-
332 TREE v.1.5.5 (or later) by implementing the posterior-mean-site-frequency (PMSF) model (Wang
333 et al., 2017), as a rapid approximation of the site-heterogeneous CAT-like mixture model (Quang et
334 al., 2008) with 60 amino-acid profile categories and the exchange rates of the LG substitution
335 matrix (option: -m LG+C60+G+F). We used the tree with the best log-likelihood that resulted from
336 the analysis based on the partition model as a guide tree. The idea of applying this mixture model
337 was to increase the biological realism of the modeled substitution processes, as it should be able to
338 describe site-specific amino-acid preferences in the supermatrices. Moreover, proponents of the
339 site-heterogeneous mixture models have recommended their use to alleviate systematic errors due
340 to model violations (Lartillot et al., 2007) We calculated the non-parametric bootstrap measure (BS
341 PMSF. Fig. 2a, 2b) when applying the PMSF model (LG+C60+G+F) with 100 replicates (Table 2).
342

343 **2.3.6 Coalescent-based phylogenetic analysis**

344 The supermatrix approach has been criticized for producing statistically inconsistent topologies
345 as it fails to account for gene tree heterogeneity due to incomplete lineage sorting (ILS) (Kubatko
346 and Degnan, 2007). However, research has shown that concatenation (even unpartitioned) can be
347 more accurate than summary species tree methods under certain conditions (Bayzid and Warnow,
348 2013; Mirarab et al., 2016; Mirarab and Warnow, 2015; Xu and Yang, 2016) and that summary
349 species tree methods can be sensitive to gene tree estimation errors or to low degree of variation in
350 the analyzed sets of loci (Bayzid and Warnow, 2013; Meiklejohn et al., 2016). In an attempt to

351 explore the sensitivity of our phylogenetic results to the above mentioned potentially biasing
352 factors, we conducted coalescent species tree analyses with ASTRAL III v.5.5.12 (Mirarab and
353 Warnow, 2015; C. Zhang et al., 2018) as an alternative to the supermatrix approach. We expected
354 that if both methods yield the same topologies for the datasets analyzed, any observed topological
355 differences (between analyzed datasets) would unlikely be due to ILS, hybridization or due to
356 biases resulting from gene tree estimation errors.

357 We performed the coalescent approach on 1) a selected subset of COGs from supermatrix E
358 and 2) the full set of COGs from supermatrix H. When analyzing supermatrix E, we discarded all
359 COGs with fewer than 13 species and more than 20 % ambiguous characters (X, -) to increase data
360 coverage of the selected genes (Sayyari et al., 2017). When analyzing supermatrix H, we selected
361 the full set of COGs to perform the species tree analysis, as this dataset had already a low
362 proportion of missing data (Table 3, Suppl. Fig. 10). Individual gene trees were constructed under
363 the maximum likelihood optimality criterion in IQ-TREE v.1.5.5. Model selection for each aaCOG
364 was restricted to the amino-acid substitution matrices DCMUT, LG, JTT, and WAG under the
365 AICc information criterion. We allowed a maximum of four free rate categories for modeling rate
366 heterogeneity among sites in ModelFinder (option: -cmax 4). We calculated the branch lengths of
367 the estimated species tree in coalescence units in ASTRAL with the option -q. We annotated the
368 species tree with the option -t 2. This resulted in a tree labeled with quartet scores, total quartet
369 support and local posterior probabilities (Sayyari and Mirarab, 2016). Quartet support values (q1,
370 q2, q3) indicate the proportion of induced quartets in the gene trees that agree or disagree with a
371 branch on the calculated species tree. Each alternative value corresponds to the three possible
372 topologies around each branch of interest. The local posterior probabilities are calculated based on
373 the quartet support values (Sayyari and Mirarab, 2016). The first quartet support and local posterior
374 probability for each branch (q1 and pp1 respectively) correspond to the topology that is depicted in
375 the tree that resulted from the coalescent based species tree analysis.

376

377 **2.4 Maximum likelihood phylogenetic analyses of nucleotide sequence data**

378 We generated the codon-based nucleotide alignment of supermatrix C, by excluding partitions
379 with IC=0 (supermatrix nt.A, Suppl. Fig. 2, Table 3). With this nucleotide supermatrix, we
380 evaluated whether or not 1) there is congruence between amino-acid and nucleotide sequence-based
381 trees, 2) excluding first and third codon positions had a topological effect in the resulting phylogeny
382 of Dytiscoidea, 3) RY-recoding of the nucleotide matrix and subsequent tree reconstruction
383 indicated that heterogeneous base composition is a confounding factor, 4) phylogenetic analyses by
384 including compositionally heterogeneous nCOGs biased tree reconstructions and 5) relative
385 evolutionary rates of COGs affected tree reconstructions. All generated nucleotide sequence
386 supermatrices (Table 3, Suppl. Fig. 2) are deposited at MENDELEY DATA (XXXXX).

387 Saturation of nucleotide substitutions at third codon positions is a well-known problem when
388 addressing deep phylogenetic relationships (Philippe et al., 2011; Xia et al., 2003) and was also
389 relevant in a recent multigene phylogenetic study of the dytiscoid relationships (Toussaint et al.,
390 2015). Additionally, nucleotide sequences with highly heterogeneous GC content in the third codon
391 positions may contribute to phylogenomic conflict (Romiguier et al., 2016). As a result, the authors
392 of many studies have excluded saturated or compositionally heterogeneous sites prior to their
393 phylogenetic analyses (e.g. Breinholt and Kawahara, 2013; Jarvis et al., 2014; Misof et al., 2014;
394 Pauli et al., 2018; Peters et al., 2017). The second codon positions are arguably the most
395 homogeneous sites among the codon triplets of a supermatrix (e.g. Misof et al., 2014; Timmermans
396 et al., 2016) and should therefore deliver the least biased results. In order to dissect the influence of
397 heterogeneous base composition or saturated substitutions on tree reconstructions, we compared the
398 results of tree reconstructions when 1) including all codon positions of supermatrix nt.A for
399 phylogenetic reconstruction, 2) including only the second codon positions and 3) recoding the
400 nucleotide supermatrix nt.A into RY character states (R: Purines, Y: Pyrimidines). The expectation

401 is that a recoded matrix should alleviate problems related to compositional heterogeneity and
402 substitution saturation, at the cost of partially eliminating phylogenetic signal.
403 We further explored the effect of masking (i.e. removing) the most compositionally
404 heterogeneous genes (nCOGs) prior to the tree reconstructions (Table 3). In order to do so, we
405 generated a decisive version of supermatrix nt.A by discarding those nCOGs with fewer than 14
406 taxa (Suppl. Fig. 2). We did not perform any tree searches for this intermediate decisive dataset.
407 Subsequently, two reduced versions of this decisive supermatrix were generated by excluding genes
408 with RCFV value greater than 0.08 (supermatrix nt.A.homogeneous1, Table 3) and by excluding
409 genes with RCFV value greater than 0.06 (supermatrix nt.A.homogeneous2, Table 3). In addition,
410 because the evolutionary rates of individual genes are often cited as an important predictor of their
411 phylogenetic utility (Doyle et al., 2015; Klopfstein et al., 2017; Yang, 1998), we explored whether
412 the relative evolutionary rates of the included sets of nCOGs biased tree reconstructions (Suppl.
413 Text 1, Table 3). Lastly, we tested whether removal of the species *S. wrasei* from supermatices nt.A
414 and nt.A.homogeneous2 affected the phylogenetic placement of Hygrobiidae (Table 3). We decided
415 to remove *S. wrasei*, because it is the species that was associated with the longest tree branches
416 among the two species of Aspidytidae when analyzing codon-based nucleotide sequence data (Fig.
417 3).
418 Ten independent tree searches were performed for each generated nucleotide dataset with IQ-
419 TREE v.1.5.5 (or later). Tree searches and model selection in ModelFinder were based on an edge-
420 linked partition model (options. -spp -gmedian -merit AICc), by considering the nCOG boundaries
421 and the GTR substitution matrix (Tavaré, 1986), and by allowing all possible combinations for
422 modeling among site rate variation. The RY recoded (in the form of binary data [0,1]) matrix was
423 analyzed with an edge-linked partition model in IQ-TREE v.1.6.8 (options: -spp -st BIN -m MFP -
424 gmedian -merit AICc). For a selection of nucleotide supermatrices, we optimized the partitioning
425 scheme in PartitionFinder v.2.1.1 by restricting the model search to GTR and GTR+G with the

426 options -raxml and -rcluster-max 5000 using the AICc information criterion. For this purpose, we
427 selected the datasets with the lowest levels of among-species compositional heterogeneity (Table
428 3). The resulting combinations of partitions and models were used as input for IQ-TREE v.1.5.5 for
429 ten additional tree searches with the edge-linked model. Statistical branch support was estimated
430 from 100 non-parametric bootstrap replicates, TBE support, 10,000 SH-like aLRT, aBayes, 1,000
431 UFBoot1 (IQ-TREE v.1.5.5), and 1,000 UFBoot2 (IQ-TREE v.1.6.8, -bnni) replicates on the
432 datasets with the optimized partitioning schemes and on supermatrix nt.A. After verifying
433 topological congruence to the maximum likelihood tree, we mapped these support values on the
434 tree with the best log-likelihood among the trees that resulted from the ten maximum likelihood
435 searches (Fig. 3, Suppl. Fig. 69). We additionally calculated 100 non-parametric bootstrap
436 replicates and TBE support for every other nucleotide sequence dataset (Table 3). The NEXUS files
437 with the optimized schemes of the supermatrices nt.B and nt.A.homogeneous2, calculated with
438 PartitionFinder, are deposited at MENDELEY DATA (XXXXX).
439

440 **2.5 Branch support tests with four-cluster likelihood-mapping and data permutations.**

441 We tested the statistical robustness of phylogenomic estimates of four selected phylogenetic
442 hypotheses (Suppl. Tables 2 and 3) by means of the four-cluster likelihood-mapping approach
443 (FcLM) on supermatrix E (Strimmer and von Haeseler, 1997). This approach considers the
444 proportion of taxon quartets in a supermatrix that support each of the three alternative topologies
445 around a specific branch of interest (for details, see also the supplementary material provided by
446 Misof et al., 2014). The formulation of each hypothesis was based on the best tree topology inferred
447 from phylogenetically analyzing supermatrix E (Fig. 2b). We assumed taxa within each group
448 definition to be monophyletic. For each FcLM test (Suppl. Tables 2 and 3) we additionally
449 permuted the original matrix in three ways as described by Misof et al. (2014) to evaluate 1)
450 whether or not the quartet support for a certain hypothesis results from genuine phylogenetic signal,

451 2) whether or not it is affected by confounding factors relating to compositional heterogeneity, 3)
452 and whether or not the distribution of missing data affected the phylogenetic results (Suppl. Text 1).
453 The FcLM approach and the permutations for testing hypotheses 1 and 3 were also applied on
454 different amino-acid and nucleotide supermatrices (see also Suppl. Text 1 and Sann et al., 2018 for
455 a description of FcLM tests applied at the nucleotide sequence level) with the same taxon group
456 definitions in an attempt to investigate the source of topological incongruence. For each
457 phylogenetic hypothesis tested, we discarded partitions or meta-partitions (if an optimized scheme
458 was calculated for the respective matrix) that were uninformative with respect to a specific taxon-
459 group definition. For the original dataset we used the same models selected during the IQ-TREE
460 tree search for the respective dataset with the option -spp. For the permuted matrices we used the
461 models LG (for amino-acid alignments) and GTR (for the nucleotide alignments) and the option -q
462 for the partition file. All four-cluster likelihood-mapping analyses were conducted using IQ-TREE
463 v.1.5.5.
464
465 **3. Results**
466 **3.1 Orthology assignment and dataset assembly**
467 On average, 2,689 transcripts per species (87 % of 3,085 COGs) passed the reciprocal best hit
468 criterion (Min.= 2,133, Max.= 2,913) during the orthology assignment step. The dataset with the
469 lowest number of assigned orthologs (2,133) was the transcriptome of the diving beetle
470 *Thermonectus intermedius,* while the transcriptome of the species *S. wrasei* was the dataset with the
471 highest number of assigned orthologous transcripts (2,913, Table 4). The average number of outlier
472 sequences per species was 0.4 % (i.e. a mean of 12 outliers per species across 2,991 gene
473 partitions). In total, 167 amino-acid (and corresponding nucleotide) sequences were removed after
474 the alignment refinement step (Suppl. Table 4). The search for ambiguously aligned regions with
475 ALISCORE resulted in the removal of a total number of 276,537 amino-acid sites from the original

476 amino-acid sequence alignments of supermatrix A (and 829,611 sites from their corresponding
477 codon-based nucleotide sequence alignments).
478
479 **3.2 Phylogenetic analyses of amino-acid sequence data**
480 The different maximum likelihood searches for the same datasets resulted in congruent
481 topologies (Fig. 2 and Suppl. Fig. 45–59) irrespective of whether or not we optimized the
482 partitioning scheme (for supermatrices E and H respectively). The phylogenetic analyses with the
483 site-heterogeneous mixture models yielded topologies identical to those obtained when using
484 partition models for the amino-acid datasets analyzed (Suppl. Fig. 49, 51, 55, 57). All phylogenetic
485 analyses inferred the monophyly Dytiscoidea as a whole and of each dytiscoid family, and
486 supported a sister group relationship between Noteridae and all remaining families of Dytiscoidea.
487 All the above relationships received high statistical support when analyzing amino-acid sequence
488 data except for the monophyly of Aspidytidae when performing FcLM analysis on supermatrix E
489 (see section 3.4.1). Moreover, a clade comprising the families Amphizoidae and Aspidytidae was
490 suggested in all maximum likelihood analyses of amino-acid sequence data and is fully supported
491 by all branch support measures (Fig. 2a and 2b). FcLM analysis on both the original and the
492 permuted data of supermatrix E indicate high support for a clade consisting of Amphizoidae and
493 Aspidytidae without detectable confounding signal (section 3.4.2, Hypothesis 2, Suppl. Table 2).
494 The phylogenetic analyses of the amino-acid supermatrices which were not corrected for
495 among-species compositional heterogeneity, suggested Hygrobiidae as the sister clade to
496 Aspidytidae + Amphizoidae with strong statistical branch support. Analyses of these datasets
497 suggested that the three families collectively form a clade sister to the diving beetles (e.g. Fig. 2b).
498 The analysis of supermatrix H (RCFV-corrected version of supermatrix F) yielded a different
499 arrangement with Hygrobiidae being placed as a sister group to (Amphizoidae + Aspidytidae) +
500 Dytiscidae (Fig. 2a). Furthermore, the phylogenetic analysis of the supermatrices J and K (RCFV-

501 corrected versions of supermatrices E and A respectively) also suggested the latter sister group
502 relationship (Suppl. Fig. 58–59). Non-parametric bootstrap support for the clade (Amphizoidae +
503 Aspidytidae) + Dytiscidae is not very high (supermatrix H: 79 %, Fig 2a, see also Suppl. Fig. 54,
504 58–59), but most measures such as BS PMSF, UFBoot1, aBayes, SH-aLRT and TBE strongly
505 support this clade.

506 The coalescent-based species tree analyses with ASTRAL yielded topologies identical to those
507 obtained from concatenation when analyzing supermatrices E and H (Suppl. Fig. 71–72). Overall,
508 the local posterior probabilities in favor of the monophyly of the dytiscoid lineages except
509 Noteridae (i.e. Aspidytidae + Amphizoidae + Dytiscidae + Hygrobiidae), the monophyly of
510 Aspidytidae, and the monophyly of Amphizoidae + Aspidytidae are high in both coalescent
511 phylogenetic analyses. On the one hand, quartet support shows conflict among the selected gene
512 trees of supermatrix E concerning the monophyly of Aspidytidae (q1=0.44; q2=0.32; q3=0.22) and
513 the placement of Hygrobiidae as a sister group to Aspidytidae and Amphizoidae (q1=0.37; q2=0.26;
514 q3=0.36). On the other hand, the local posterior probabilities for the above relationships are high
515 (0.99 and 0.90 respectively). A low quartet support for the monophyly of Aspidytidae is again
516 observed when analyzing the gene trees of supermatrix H (q1=0.45; q2=0.32; q3=0.21), indicating
517 conflict among the gene trees of this dataset for this relationship. A clade comprising Amphizoidae,
518 Aspidytidae, and Dytiscidae (which resulted from the coalescent analysis of the genes in
519 supermatrix H) received low quartet support (q1=0.37; q2=0.36; q3=0.26). This clade also received
520 low support based on the local posterior probability value (0.73).

521

522 **3.3 Phylogenetic analyses of nucleotide sequence data**

523 In contrast to the analysis of the amino-acid sequence data, phylogenetic analysis of the codon-
524 based nucleotide sequence data (supermatrix nt.A) yielded paraphyletic Aspidytidae, with *S. wrasei*
525 placed as a sister taxon of Amphizoidae (Fig. 3b). However, after removal of the most

526 compositionally heterogeneous genes, the phylogenetic analyses provided strong statistical branch
527 support for the monophyly of Aspidytidae (Fig. 3a, Suppl. Fig. 65–67). Analyzing exclusively
528 second codon positions also provided strong support for the hypothesis of Aspidytidae representing
529 a natural group (Suppl. Fig. 60 and 69). The best tree from the analysis of the RY-recoded
530 supermatrix supported the monophyly of Aspidytidae as well (Suppl. Fig. 70). Some of the
531 interfamiliar relationships recovered by the analysis of the recoded nucleotide sequence matrix are
532 different than the relationships recovered from most of our analyses. The branch support values for
533 those relationships are high but the internal branches of the tree are very short (Suppl. Fig. 70). As
534 expected, including only the fastest evolving genes in the dataset delivered phylogenetic
535 relationships (including paraphyletic Dytiscoidea) not seen in any of the other phylogenetic
536 analyses. In contrast, removing the ca. 25 % or 75 % of the fastest evolving genes did not result in
537 topological alterations compared with the original results of the analysis of supermatrix nt.A
538 (Suppl. Fig. 61 and 63). Phylogenetic analyses of the concatenated codon-based nucleotide
539 sequence dataset after removing outlier genes with respect to their relative evolutionary rate (Suppl.
540 Fig. 64), yielded the same topology as the analysis of the supermatrix composed of exclusively
541 slowly evolving genes (Suppl. Fig. 61).

542 Analysis of the nucleotide datasets did not corroborate the hypothesis of Hygrobiidae being the
543 sister group to a clade comprising Aspidytidae, Dytiscidae and Amphizoidae, except when
544 analyzing exclusively second codon positions. One additional difference between the trees derived
545 from analyzing codon-based nucleotide sequence data and the tree based on the analysis of
546 exclusively second codon positions is the placement of Amphizoidae as the sister group of
547 Dytiscidae (Suppl. Fig. 60 and 69). However, this placement is in conflict with the phylogenies
548 inferred when analyzing amino-acid data and which suggested a sister group relationship of
549 Amphizoidae and Aspidytidae (Fig. 2) with high support. The results of the FcLM analysis on the
550 amino-acid supermatrix E (Suppl. Table 3) are also in support of a clade Amphizoidae +

551 Aspidytidae without detectable confounding signal (see section 3.4.1). Removal of the species *S.*
552 *wrasei* from the selected codon-based datasets (nt.A and nt.A.homogeneous2) did not affect the
553 phylogenetic placement of Hygrobiidae (Suppl. Fig. 67–68). However, after removal of *S. wrasei*
554 from the compositionally homogeneous matrix the monophyly of (Amphizoidae + Aspidytidae) +
555 Hygrobiidae is only weakly supported (Suppl. Fig. 67).
556

557 **3.4 Branch support tests with four-cluster likelihood-mapping and data permutations**

558 **3.4.1 Monophyly of Aspidytidae**

559 All trees based on the MSAs of amino-acid sequences recovered a monophyletic Aspidytidae.
560 The FcLM analysis of the amino-acid sequence data did not, however, strongly support the
561 monophyly of Aspidytidae (Fig 2c: 55 % of quartets support a monophyletic Aspidytidae when
562 analyzing the original data of supermatrix E). The FcLM results when analyzing supermatrix E
563 show some weaker signal for the placement of *A. niobe* as sister group to Amphizoidae (40 % of
564 quartets). Additionally, after eliminating phylogenetic signal in supermatrix E (permutation scheme
565 I) putative confounding signal emerges supporting the monophyly of Aspidytidae (75 % of
566 quartets). This signal is reduced after having applied permutation scheme II on supermatrix E (40 %
567 of quartets), suggesting that it stems from non-stationary processes among species in supermatrix E
568 (Suppl. Table 2). When the effect of among-species compositional heterogeneity is reduced in the
569 original data (supermatrices H and K), the putative confounding signal supporting the monophyly
570 of Aspidytidae decreases (25 % and 20 % of quartets, permutation scheme I, supermatrix H and K
571 respectively) and the support for the monophyly of Aspidytidae when analyzing the original data
572 increases (60 % of quartets are in favor of the monophyly of Aspidytidae when analyzing the
573 original data of supermatrices H and K).

574 Maximum likelihood phylogenetic analysis of the supermatrix nt.A strongly supports the sister
575 group relationship between *S. wrasei* and Amphizoidae, as indicated by all applied branch support

576 measures (Fig. 3b). This arrangement also received relatively high quartet support from the FcLM
577 analysis on the original data of supermatrix nt.A (70 % of quartets, Suppl. Table 3). There is
578 however strong putatively confounding phylogenetic signal in favor of this hypothesis after
579 applying permutation scheme I on supermatrix nt.A (70 % of quartets). This signal is greatly
580 reduced in permutation number II of the same matrix (20 % of quartets), suggesting that it stems
581 from non-stationary processes among species in the supermatrix nt.A. The total number of different
582 quartets that are informative with respect to the monophyly of Aspidytidae is low (20 quartets,
583 Suppl. Table 2) due to the low number of species in our dataset.
584
585 **3.4.2 Phylogenetic relationships of the dytiscoid families**
586 In all our tree reconstructions, Noteridae were inferred as the sister taxon of all remaining
587 Dytiscoidea (e.g. Fig. 2a, 2b, 3a, 3b). This phylogenetic placement received strong support from
588 most applied statistics, and is also supported by the FcLM and data permutation tests on
589 supermatrix E (100 % of quartets support a clade of Dytiscidae + Hygrobiidae + Amphizoidae +
590 Aspidytidae as the sister group of Noteridae, Suppl. Table 2, Hypothesis 4). In addition, a clade of
591 Aspidytidae + Amphizoidae is fully supported by all analyses based on the amino-acid and
592 nucleotide sequences, except for the analyses of the second codon positions (Suppl. Fig. 60 and 69).
593 We observed a strong signal in favor of Amphizoidae + Aspidytidae when analyzing the original
594 data of supermatrix E (95.3 % of quartets support Amphizoidae + Aspidytidae, Suppl. Table 2), and
595 no detectable confounding signal for this arrangement after applying permutation scheme I on the
596 same amino-acid dataset (39.1 % of quartets support Amphizoidae + Aspidytidae when eliminating
597 phylogenetic signal in supermatrix E).
598 The position of Hygrobiidae with respect to Amphizoidae, Aspidytidae and Dytiscidae differs
599 between the trees that were inferred at the amino-acid sequence level when allowing for different
600 degrees of compositional heterogeneity among species in the dataset (e.g. Fig. 2). The two

601 prevailing phylogenetic hypotheses that were inferred from analyzing amino-acid sequence data
602 (Fig. 2a and 2b) received almost equally high support in the FcLM analyses of the different amino-
603 acid and nucleotide data matrices with no detectable confounding factors (Fig. 2d, Suppl. Tables 2
604 and 3). This result indicates the substantial phylogenetic conflict among the analyzed quartets for
605 this particular phylogenetic question. Again, the total number of quartets for investigating the
606 phylogenetic hypothesis number 3 was not very high (128 quartets) due to taxon sampling
607 limitations in our dataset.
608
609 **4. Discussion**
610 **4.1 The phylogeny of the dytiscoid families and the monophyly of Aspidytidae**
611 Previous analyses based on either morphological or molecular data were unable to deliver
612 congruent reconstructions of dytiscoid phylogenetic relationships (e.g. Baca et al., 2017; Balke et
613 al., 2008, 2005, Beutel et al., 2013, 2008; Toussaint et al., 2015). We addressed these phylogenetic
614 problems with an unprecedented amount of phylogenomic data representing all dytiscoid families
615 except Meruidae. Results of our phylogenomic analyses are consistent with the hypothesis of
616 Noteridae (plus most likely Meruidae) being the sister group of a clade comprising the families
617 Amphizoidae, Aspidytidae, Dytiscidae, and Hygrobiidae (Baca et al., 2017; Beutel et al., 2008;
618 Dressler et al., 2011; McKenna et al., 2015). The monophyly of the latter clade received strong
619 statistical support in all of our analyses. The phylogenetic relationships within this clade, however,
620 are not robustly resolved and resolution depends on the phylogenetic approach and dataset.
621 Nevertheless, our analyses demonstrate that selecting the datasets that violate model assumptions
622 the least support a sister group relationship between Hygrobiidae and a clade comprising
623 Amphizoidae, Aspidytidae, and Dytiscidae. The monophyly of the latter three families is also
624 suggested by an unusual morphological apomorphy, a pair of large and sclerotized epipharyngeal
625 sensilla (Dressler and Beutel, 2010). A clade comprising the squeak beetles and the diving beetles

626 (Hygrobiidae + Dytiscidae), as suggested by some studies based on the analysis of morphological
627 characters (e.g. Alarie and Bilton, 2005; Beutel et al., 2013; Beutel and Roughley, 1988; Dressler et
628 al., 2011) was not recovered in any of our analyses. This suggests that prothoracic glands (Forsyth,
629 1970) have evolved independently in the two families.

630 All analyses of amino-acid sequence data and nucleotide sequence data with reduced levels of
631 among-species compositional heterogeneity suggest monophyletic Aspidytidae. This result is
632 congruent with the analysis of the morphological characters of the adults of Aspidytidae (Balke et
633 al., 2003). Moreover, we received high branch support and high FcLM support for a clade
634 consisting of Amphizoidae and Aspidytidae in all analyses of amino-acid sequence data, and this
635 phylogenetic relationship is also supported by the analysis of codon-based nucleotide sequence
636 data. On the other hand, the analysis of second codon positions suggested a sister group relationship
637 of Amphizoidae and Dytiscidae. The cause of this incongruent result is unclear, but may be due to
638 insufficient or conflicting signal for this relationship in the second codon positions. Overall, we
639 consider a sister group relationship of Amphizoidae and monophyletic Aspidytidae as the most
640 plausible scenario suggested by our data.

641 The disjunct geographical distribution of Amphizoidae, Aspidytidae and Hygrobiidae in
642 combination with the extensive molecular divergence among the three families, and between the
643 two aspidytid species in particular, suggests that these groups represent old and relictual lineages. In
644 this aspect, we corroborate the results put forth by Toussaint et al. (2015) and Hawlitschek et al.
645 (2012), who came to similar conclusions, but these conclusions were based on phylogenetic results
646 from only a few molecular loci. Thus, our results provide a base line for future phylogenomic
647 analyses of dytiscoid relationships and help to identify the most pressing open questions.
648 Additionally, we want to emphasize that the disjunct, relict and micro-endemic distribution of
649 Aspidytidae demands appropriate actions to conserve their habitats and future existence.

650 The instability of the phylogenetic placement of Hygrobiidae among the different datasets
651 analyzed deserves special attention. The lack of resolution in phylogenetics is often attributed to
652 biological phenomena of ancient rapid cladogenesis (Whitfield and Kjer, 2008). Signatures of such
653 processes when analyzing genome-scale data are illustrated by either low levels of phylogenetic
654 signal or highly conflicting phylogenetic signal (Suh, 2016; Whitfield and Kjer, 2008). Our FcLM
655 results as well as the coalescent analyses showed substantial levels of phylogenomic conflict for the
656 interrelationships of the dytiscoid families Amphizoidae, Aspidytidae and Hygrobiidae. The large
657 molecular divergence observed between these families and within Aspidytidae, together with their
658 disjunct geographical distributions and the high levels of gene tree conflict for the interfamiliar
659 relationships observed here, are indications that these lineages may have originated via rapid
660 cladogenesis. On the other hand, such ancient rapid speciation events can be difficult to distinguish
661 from other causes related to data quality and conflict in the analyzed datasets (Whitfield and Kjer,
662 2008) and this hypothesis should be further tested using molecular dating and diversification
663 analyses.
664 The lack of phylogenetic resolution can be the result of deficient taxon sampling (Nabhan and
665 Sarkar, 2012). We acknowledge the sensitivity of phylogenetic reconstructions to taxon sampling,
666 yet we consider our dataset as the most comprehensive genome-scale dataset to date in terms of the
667 number of included species within the small families Amphizoidae, Aspidytidae and Hygrobiidae.
668 Furthermore, we acknowledge that the statistical power of the FcLM approach is highly dependent
669 on the number of sampled species. Increasing the available genomic data, especially within the
670 species-rich Dytiscidae and Noteridae, will inevitably boost the statistical power of the FcLM
671 analyses and further facilitate addressing the persisting phylogenetic uncertainties. Lastly, the
672 analysis of other kind of data such as whole genome sequences, and genomic meta-characters can
673 provide additional or complementary evidence to decipher the evolutionary history of Dytiscoidea
674 (Niehuis et al., 2012).

675

676 4.2 Model violations bias the reconstruction of the phylogeny of Dytiscoidea

677 We pointed out that model violations are one very likely source of the observed phylogenetic
678 discrepancies among the different datasets that we analyzed. This is not an unknown phenomenon,
679 as violations of model assumptions, uneven distribution of data coverage, data-type effects, or
680 unnoticed cross-contamination are some of the factors that can strongly bias the results of tree
681 reconstructions (Borowiec et al., 2019; Feuda et al., 2017; Jeffroy et al., 2006; Jermiin et al., 2004;
682 Nesnidal et al., 2013; Philippe et al., 2011; Reddy et al., 2017; Whitfield and Kjer, 2008). In the
683 presented analysis of the dytiscoid relationships we are able to show that masking the genes with
684 the highest levels of among-species compositional heterogeneity altered the topologies of the
685 inferred phylogenetic trees. This was the case irrespective of whether or not we analyzed amino-
686 acid sequence data or nucleotide sequence data. We deduce from this that scientists should seek to
687 take measures against violations of model assumptions in order to more accurately infer the real
688 evolutionary history of the taxa of interest.

689 At the amino-acid sequence level, we reconstructed phylogenetic relationships of Dytiscoidea
690 based on three supermatrices for which the most compositionally heterogeneous genes had been
691 removed (supermatrices H, J, and K). All of these reconstructions yielded congruent topologies,
692 with respect to the interrelationships of the dytiscoid families, which differed from the topologies
693 that resulted from the analyses of the compositionally heterogeneous amino-acid sequence datasets.
694 The effects of among-species compositional heterogeneity at the amino-acid sequence level is
695 further corroborated by our FcLM tests. Although Aspidytidae are recovered as a monophylum
696 when analyzing amino-acid sequence data, there is detectable confounding signal supporting this
697 monophyly in the compositionally heterogeneous supermatrix E. This putatively confounding
698 signal most likely stems from compositional heterogeneity among species in the alignment because
699 it is reduced when analyzing the datasets with reduced levels of among-species compositional

700 heterogeneity. Furthermore, despite the fact that phylogenetic analysis of both the compositionally
701 homogeneous and the compositionally heterogeneous amino-acid datasets yielded monophyletic
702 Aspidytidae, the compositionally homogeneous supermatrices showed slightly increased
703 phylogenetic signal supporting the monophyly of Aspidytidae. We conclude from these
704 observations that gene partitions with high degrees of among-species compositional heterogeneity
705 biased some of our phylogenetic analyses and are one very likely source of incongruence between
706 tree topologies inferred from analyzing amino-acid sequence data.

707 Summary coalescent phylogenetic analyses (Mirarab and Warnow, 2015) suggested topologies
708 identical to those obtained when applying a concatenation approach. The observation that both
709 approaches resulted in the same topology irrespective of what dataset we analyzed makes us
710 confident that the incongruence between topologies of different datasets are not due to high levels
711 of incomplete lineage sorting or ancient introgression. This observation further suggests that the
712 applied summary species tree method is sensitive to the same compositional bias as the supermatrix
713 approach.

714 Our results showed that reducing the degree of missing data and indecisive gene partitions in
715 the amino-acid supermatrices did not affect the topology of the reconstructed dytiscoid phylogeny.
716 The analysis of the amino-acid sequence supermatrix with 100 % data coverage across all species
717 delivered the same topology as the analyses of the non-homogeneous datasets, further supporting
718 the idea that non-random distribution of missing data unlikely accounts for the observed topological
719 differences. Additionally the use of site-heterogeneous amino-acid mixture models in a maximum
720 likelihood framework yielded identical topologies compared with the analysis based on site-
721 homogeneous partition models. The overall information content of the supermatrices (Misof et al.,
722 2013) could not be related to the topological incongruence.

723 It has been argued that alignment masking might be detrimental to reliable phylogenetic
724 reconstructions (Tan et al., 2015). Tan and colleagues (2015) argue that alignment masking

725 eliminates too much phylogenetic signal and therefore reduces the resolution of single-gene
726 phylogenetic inferences. We found no evidence that alignment masking affected the topology of the
727 dytiscoid phylogeny in the analyses of concatenated and masked aaCOGs.

728 The analysis of the nucleotide sequence data revealed that first and third codon positions are
729 heterogeneous in their base composition, because their inclusion results in a major deviation from
730 SRH conditions. Congruently, the Bowker's pairwise symmetry tests corroborate previous
731 hypotheses that the smallest deviations from SRH conditions are consistently observed in datasets
732 composed solely of second codon positions. Reducing among-species compositional heterogeneity,
733 by recoding the nucleotide sequence data or by removing compositionally heterogeneous genes,
734 restored the monophyly of the cliff water beetles, congruent with tree reconstructions based on the
735 amino-acid sequence datasets. These results indicate that the paraphyly of Aspidytidae as it was
736 found by Toussaint et al. (2015) could also be an artifact resulting from compositional biases in the
737 underlying dataset. Additional evidence for the effect of compositional bias on the analysis of the
738 nucleotide sequence data comes from the results of the FcLM. The FcLM results on supermatrix
739 nt.A suggest that the paraphyletic Aspidytidae stems from non-stationary processes among species
740 in the analyzed dataset, as the signal in favor of this relationship is greatly reduced when applying
741 permutation scheme II. The FcLM results of the nucleotide matrix after reducing among-species
742 compositional heterogeneity shows that there is weak signal supporting the original results (40 %)
743 but there are no detectable confounding effects observed for this arrangement. Taken together these
744 results suggest that the observed paraphyly Aspidytidae obtained when analyzing supermatrix nt.A
745 probably stems from systematic bias owing to among-species compositional heterogeneity in first
746 and third codon positions.

747 We compared the resolution of three distinct sets of genes relative to their evolutionary rate and
748 found that except for the set of genes with the highest relative evolutionary rates, the selection of
749 gene sets did not influence the results. In the extreme case of analyzing a set of the ca. 25 % of the

750 fastest evolving genes in our supermatrix, we recovered many unexpected relationships, which in
751 turn suggests that including only fast evolving genes results in erroneous phylogenetic estimates of
752 the dytiscoid relationships. Analyses based on the 25 % of the most slowly evolving genes yielded
753 results congruent with those obtained when analyzing all genes (i.e., those of supermatrix nt.A). We
754 also find that after extending the phylogenetic analysis to the 75 % of the slowest evolving genes
755 (i.e. by removing only the 25 % of the fastest evolving genes), the relationships recovered are the
756 same as when analyzing supermatrix nt.A, including the paraphyly of Aspidytidae. Hence, we
757 hypothesize that the paraphyly of Aspidytidae, obtained when analyzing the nucleotide sequence
758 data of supermatrix nt.A, is very likely not driven by the confounding effects of genes with very
759 high evolutionary rates.
760
761 **5. Conclusions**
762 Our extensive phylogenomic analyses resolve some outstanding issues in adephagan beetle
763 phylogeny, as well as pointing to some problems which apply to phylogenomic approaches more
764 generally. We present evidence that the cliff water beetles (Aspidytidae) constitute a monophylum
765 despite their highly disjunct geographical distribution and large molecular divergence. In addition,
766 our analyses suggest that Aspidytidae are the closest relatives of Amphizoidae. The close affinity of
767 Amphizoidae and Aspidytidae is supported by most of our phylogenetic analyses and by FcLM
768 tests of amino-acid sequence data. Our study could not provide conclusive evidence for some of the
769 interfamiliar relationships of Dytiscoidea, yet we show that excluding genomic regions with high
770 among-species compositional heterogeneity yields different topologies for our transcriptomic
771 dataset. After accounting for most potential tree confounding factors, we consider a sister group
772 relationship between Hygrobiidae and a clade comprising Amphizoidae, Aspidytidae, and
773 Dytiscidae to most likely represent the evolutionary relationships. Overall, we demonstrated in our
774 study how confounding parameters can lead to misleading results. Our study also highlights the

775 importance of interpreting, integrating and summarizing across different datasets and tree-inference
776 approaches for drawing major phylogenetic conclusions. It is obvious that incongruence due to
777 model violations, uneven distribution of missing data, unequal evolutionary rates, as well as
778 conflicting phylogenetic signal among gene trees will prevail in primarily sequence-based
779 phylogenomic analyses, and measures need to be taken against violations of model assumptions. An
780 alternative or complementary route would be the comparative analyses of genomic meta-characters
781 such as the position of introns, the evolution of gene families, or the structure of genes. The
782 tremendous advances in sequencing technologies are currently opening a window into these fields
783 of research (Niehuis et al., 2012).

784

785 **Acknowledgments**

786 This study has partially been enabled by the 1KITE consortium. (www.1kite.org). AV, BM, MB,
787 ON and RGB thank the German Research Foundation (BM649/15-1, NI 1387/7-1, BA2152/24-1)
788 which partially provided funding for this project. MB thanks the Mohammed bin Zayed Species
789 Conservation Fund (MBZ) for a grant to study the Chinese Aspidytidae. RMW is grateful to the
790 Swiss National Science Foundation (PP00P3_170664). Funding for transcriptome sequencing and
791 assembly was in part supported by BGI-Shenzhen. We are grateful to the 1KITE beetle subproject
792 (http://www.1kite.org/subprojects.html) for granting access to a few transcriptomes prior to their
793 planned release. We thank Alexandra Cieslak and Ignacio Ribera for providing transcriptome
794 sequence data for our preliminary analyses. We also thank Bui Quang Minh (Australian National
795 University) and Ondrej Hlinka (CSIRO) for helpful comments and help with the HPC cluster during
796 the analyses of our data.

797

798

799

800 **Authors' contributions**

801 AV, BM, MB, ON, and RGB conceived the study. BM, DRM, MB, ON, RSP, and XZ contributed
802 to coordination of taxon sampling and transcriptome sequencing. BM, DRM, MB, ON, RGB, and
803 XZ, contributed to funding acquisition. DRM, DTB, FJ, HEE, KM, LH, MB, RSP, YA, and XZ
804 collected samples and/or contributed to the data processing of the sequenced transcriptomes. AD,
805 AV, JMP, LP, and SL performed the *de novo* transcriptome assembly and cross-contamination
806 checks. AD, AV, and JMP performed the NCBI sequence submissions. AV, ON, and RMW
807 performed the orthology inference and orthology assignment analyses. AV performed the
808 phylogenetic analyses with contributions, suggestions and comments from BM, KM, and CM. AV,
809 BM, ON, MB and RGB wrote the first draft of the manuscript, with AV taking the lead. All authors
810 contributed with comments and suggestions in the later versions of the manuscript.

1175 **Table 1**: An overview of the newly sequenced and previously published transcriptomes that were
1176 analyzed in the present study. NCBI accession numbers and descriptive statistics to each
1177 transcriptome are provided. Species whose transcriptomes were analyzed are given in alphabetic
1178 order.
1179
1180 **Table 2**: Detailed information and statistics of each generated amino-acid supermatrix analyzed in
1181 this study. The overall alignment completeness score of each matrix was calculated with the
1182 software AliStat. Matrix phylogenetic information content and saturation were calculated with the
1183 software MARE. The RCFV value was calculated with BaCoCa. Pairwise tests of symmetry for the
1184 Bowker's test were performed with SymTest. (C_a: overall alignment completeness score, SV:
1185 matrix saturation values, IC: matrix phylogenetic information content).
1186
1187 **Table 3**: Detailed information and statistics of each generated nucleotide supermatrix analyzed in
1188 this study. The overall alignment completeness score of each matrix was calculated with AliStat.
1189 Pairwise tests of symmetry for the Bowker's test were performed with SymTest. Median p-values
1190 0.00E+00 for the Bowker's test indicate very small numbers. (C_a: Overall alignment completeness
1191 score).
1192
1193 **Table 4**: Summarized statistics of the results of the transcript orthology assignment at the amino-
1194 acid sequence level. Species whose transcriptomes were analyzed are given in alphabetic order. The
1195 summary statistics were calculated with the helper scripts provided with the Orthograph package.

1225 **(Figures of the main text should be colored only in the online version of the article. The**
1226 **figures should be used in double-column format)**
1227
1228 **Figure 1**: Overview of different phylogenetic hypotheses on family phylogenetic relationships
1229 among Dytiscoidea proposed in previous studies that had analyzed molecular and morphological
1230 data. (Note that Meruidae were not included in all studies. However, since their sister group
1231 relationship to Noteridae is generally considered undisputed, we consistently included them in the
1232 overview: "Meruidae + Noteridae"). a) Balke et al. (2005) based on morphological data, b) Baca et
1233 al. (2017) based on UCE data, c) Beutel et al. (2013, 2006) based on morphological data, d) Ribera
1234 et al. (2002a) based on morphological and molecular data, e) Balke et al. (2005, 2008) based on
1235 molecular data and Balke et al. (2005) based on morphological and molecular data, f) Toussaint et
1236 al. (2015) based on molecular data and McKenna et al. (2015) based on molecular data with only
1237 *Aspidytes* included.
1238
1239 **Figure 2**: Different phylogenetic hypotheses deduced from the analysis of amino-acid sequence
1240 data. a) Phylogram with the best log-likelihood score on the optimized scheme of supermatrix and
1241 b) phylogram with the best log-likelihood score on the optimized scheme of supermatrix E. Branch
1242 support is denoted based on 100 non-parametric bootstrap replicates (BS), 100 non-parametric
1243 bootstraps based on the PMSF model (BS PMSF), 10,000 SH-like aLRT replicates (SH-aLRT),
1244 aBayes support, 1,000 Ultrafast Bootstraps 1 (UFBoot1), 1,000 Ultrafast Bootstraps 2 (UFBoot2, -
1245 bnni), and 100 bootstraps by transfer (TBE). Both trees are rooted with Gyrinidae. Congruent and
1246 incongruent clades between the two trees (in terms of included terminal taxa) are illustrated in
1247 different colors. c) Results of the FcLM analysis on the original data of supermatrix E for the
1248 phylogenetic hypothesis 1 (i.e. monophyly of Aspidytidae). d) Results of the FcLM analysis on the
1249 original data of supermatrix E for the phylogenetic hypothesis 3 (i.e. Hygrobiidae are the sister

1250 group of Amphizoidae + Aspidytidae). Beetle photos: 1) *Sinaspidytes wrasei*, 2) *Noterus*
1251 *crassicornis*, 3) *Hygrobia hermanni*, 4) *Amphizoa lecontei*, 5) *Cybister lateralimarginalis* (photos
1252 and copyright: M. Balke).

1253

1254 **Figure 3**: Comparison of phylogenetic hypotheses resulted from the analysis of the codon-based
1255 nucleotide sequence data. Congruent and incongruent clades between the two trees (in terms of
1256 included terminal taxa) are illustrated in different colors. a) Phylogram with the best log-likelihood
1257 score on the optimized scheme of supermatrix nt.A.homogeneous2. b) Phylogram with the best log-
1258 likelihood score on the unoptimized partitioning scheme of supermatrix nt.A. Branch support is
1259 denoted based on 100 non-parametric bootstrap replicates (BS), 10,000 SH-like aLRT replicates
1260 (SH-aLRT), aBayes support, 1,000 Ultrafast Bootstraps 1 (UFBoot1), 1,000 Ultrafast Bootstraps 2
1261 (UFBoot2, -bnni), and 100 bootstraps by transfer (TBE). Both trees were rooted with Gyrinidae.
