Ocean community warming responses explained by thermal affinities and temperature gradients

Michael T. Burrows^{1*}, Amanda E. Bates^{2,3}, Mark J. Costello⁴, Martin Edwards^{5,6}, Graham J. Edgar⁷, Clive J. Fox¹, Benjamin S. Halpern^{8,9,10}, Jan G. Hiddink¹¹, Malin L. Pinsky¹², Ryan D. Batt¹², Jorge García Molinos^{13,14}, Benjamin L. Payne¹, David Schoeman^{15,16}, Rick D. Stuart-Smith⁷, Elvira S. Poloczanska^{17,18}

As ocean temperatures rise, species distributions are tracking towards historically cooler regions in line with their thermal affinity^{1,2}. However, different responses of species to warming and changed species interactions makes predicting biodiversity redistribution and relative abundance a challenge^{3,4}. Here we use three decades of fish and plankton survey data to assess how warming changes the relative dominance of warm-affinity and cold-affinity species^{5,6}. Regions with stable temperatures show little change in dominance structure (Northeast Pacific, Gulf of Mexico), while warming sees strong shifts towards warm-water species dominance (North Atlantic). Importantly, communities whose species pools had diverse thermal affinities and narrower range of thermal tolerance show greater sensitivity, as anticipated from simulations. Composition of fish communities changed less than expected in regions with strong temperature depth gradients. There, species track temperatures by moving deeper^{2,7}, rather than horizontally, analogous to elevation shifts in land plants⁸. Temperature thus emerges as a fundamental driver for change in marine systems, with predictable restructuring of communities in the most rapidly warming areas using metrics based on species thermal affinities. The ready and predictable dominance shifts suggests a strong prognosis of resilience to climate change for these communities.

Abundance and distributions of marine species are changing in response to anthropogenic climate change¹ but these changes vary geographically and across taxa. Shifts in geographical range and temporal species turnover, for example, tend to be accelerated where temperature changes coincide with widely spaced isotherms^{1,2}. Unlike terrestrial ecosystems, marine species may be unable to shelter

28 from extreme temperatures, making the effect of ambient temperature immediate, unavoidable, and
29 easier to detect. Local gain and loss of species, combined with changes in the relative abundance of
30 species with different thermal affinities, drive change in community structure. On land, failure of
31 species distributions to track temperature means that community thermal composition lags behind
32 expected change, seen in communities of birds, butterflies, and plant species^{5, 9, 10, 11, 12, 13, 14}.
33 Identifying the aspects of community change that can be accurately forecasted is needed to assist
34 managers to adaptively deal with ecosystem change.

35 We use time series of species incidence in standardised international surveys of plankton and
36 demersal (seabed-living) species since 1985 (Supplementary Table 1) to quantify regional changes in
37 community structure. Combined with estimates of species' thermal affinities, these data describe
38 regional changes in the average thermal affinity of marine communities, as measured by the
39 Community Temperature Index (CTI, Supplementary Table 2). CTI is the community-wide average of
40 species' thermal affinities, which are calculated from each Species Temperature Index, STI (the median
41 of sea surface temperatures across each species' estimated geographical range, see Methods and Fig.
42 1a). The variation of thermal affinities among species (Community Thermal Diversity, CTDiv) is here
43 described by the incidence-weighted standard deviation of STIs. Low values of thermal diversity reflect
44 communities composed of species with similar STIs, and high values reflect communities composed of
45 a mix of warm- and cold-water species. The incidence-weighted average width of species' thermal
46 ranges (STRs, Fig. 1a), the Community Thermal Range (CTR), indicates whether communities are
47 composed of broad-ranged species (eurytherms) or narrow-ranged species (stenotherms). The fact that
48 distributions of marine ectotherms generally fill their thermal tolerances¹⁵ supports the inference that
49 thermal range can be approximated by species' geographic range.

50 The difference between CTI and local temperature (used to define STIs) is termed community
51 thermal bias: positive where communities are dominated by species from warmer areas, implying
52 reduced sensitivity to warming¹⁶, and negative for communities dominated by species from colder
53 areas, implying increased vulnerability¹⁷. Less compositional change in response to temperature is
54 expected in areas of strong vertical and horizontal gradients in ocean temperature (and low velocity of
55 climate change¹⁸) because small shifts may allow species to remain in the same temperature as before.
56 Thermal bias is distinct from CTI lag⁵ or extinction debt, since it refers to the difference in spatial
57 patterns of temperature and average thermal affinity rather than to a perceived delay in community
58 response to temperature change.

59 We focused on the sensitivity of CTI to regional temperature change (sCTI), defined as the ratio of
60 the change in CTI through time to the corresponding change in environmental temperature. We
61 evaluated the influence of community thermal diversity and community thermal range on CTI
62 sensitivity by developing quantitative expectations from simulations. These simulated communities
63 comprised pools of species with a thermal diversity set by the standard deviation of STI values. Each
64 species had incidence-temperature curves¹⁹ defined by their thermal range (Gaussian Fig. 1a, other
65 forms in Supplementary Fig. 1), consistent with organisms more abundant near the middle of their
66 range^{20,21}. While contested²², the Gaussian pattern holds for our fish and plankton datasets (Fig. 1b,
67 Supplementary Fig. 3) when abundance and incidence data are expressed relative to thermal range
68 location. We used species' thermal ranges and temperature changes to simulate changes in species
69 incidence with temperature which, when aggregated across species, produced changes in CTI.
70 Simulated CTI sensitivity was large where thermally diverse communities were made up of narrow-
71 ranged species¹⁷ (Fig. 1c, g), but smaller where thermal ranges were broad or thermal diversity was low
72 (Fig. 1d, f, g). For functions with declining abundance from a central maximum, simulated CTI
73 sensitivity suggested more change in thermally diverse communities made up of small-ranged species,

74 and less in communities of species with similar thermal affinities and large thermal ranges
75 (Supplementary Fig. 2, Supplementary Table 4). With Gaussian curves, CTI sensitivity was
76 proportional to the squared ratio of thermal diversity to average range width (Fig 1g and
77 Supplementary Table 2), independent of thermal bias. Below we explored this hypothesized
78 relationship with empirical data.

79 Spatial patterns in CTI for demersal species and plankton, averaged from 1985 to 2014, broadly
80 followed patterns in surface temperatures in the HadISST1 dataset²³ and seabed temperatures from the
81 Hadley Centre EN4 dataset²⁴ (Supplementary Figs. 5a, 9a). Community thermal diversity was highest
82 midway along thermal gradients. Thermal ranges were larger for plankton than demersal species, with
83 plankton thermal ranges increasing in size with latitude (Supplementary Figs. 5b, 6). Average species'
84 thermal affinity and range width in 2° grid cells were positively correlated in cool-temperate latitudes,
85 where cold-affinity species having smaller thermal ranges than those from lower latitudes, and
86 negatively correlated towards sub-tropical areas (Supplementary Fig. 6d). This pattern results from the
87 bounds on species thermal ranges at the equator and the poles (Supplementary Figs 5, 6).

88 For SST-derived CTIs, areas with strong vertical temperature gradients had more negative
89 community thermal bias in demersal species (Fig. 3a), with species' STIs more associated with cooler
90 subsurface (50-100 m) rather than surface temperature. Plankton community thermal bias was less
91 influenced by vertical gradients, suggesting a stronger association with surface temperatures. CTI
92 derived from seabed temperature was more weakly associated with the spatial pattern in SBT
93 (Methods, Supplementary Fig. 9g).

94 Both plankton and demersal communities, aggregated over 2° areas, changed in thermal affinity
95 from 1985 to 2014 (Fig. 2, Supplementary Fig. 8) at local (<500 km) to ocean-basin scales (10,000
96 km). Sea surface temperatures warmed across the North Atlantic over this period by up to 0.5°C per

97 decade, but cooled slightly or stayed the same in the Northeast Pacific (Fig. 2a,b). Regional trends in
98 CTI for plankton and for demersal fish and invertebrates more clearly followed trends in sea surface
99 temperature ($R^2 = 0.23$, Fig. 2e) than seabed temperature ($R^2 = 0.1$ Supplementary Fig. 9g). Demersal
100 communities shifted towards dominance by warm-water species around northeast USA and Europe,
101 while North Pacific, southeast USA and other areas with little temperature change had stable CTIs (Fig.
102 2c). CTI changes in plankton communities were also most pronounced in areas of greater SST change
103 in the northwest Atlantic and the northwest European Shelf (Fig. 2d).

104 In European waters, CTI for demersal species changed more consistently than plankton CTI (Fig.
105 2c,d), especially in the southern North Sea, despite observed large distribution changes in plankton
106 species²⁵. Reduced CTI sensitivity in plankton is expected given the greater temperature ranges of
107 plankton species compared to demersal invertebrates and fishes (Supplementary Figs 5c, 6d). The
108 positive effect of thermal diversity and inverse effect of community thermal range (CTR) on CTI
109 sensitivity explained much of the variability in responses of community composition to warming
110 ($R^2=0.39$), but the negative and near-zero response of Canadian demersal communities remained (Fig.
111 3c). Vertical gradients in temperature (up to 7°C over the top 50m) explained much of the remaining
112 variation in sensitivity of CTI to temperature, improving the performance of regression models (Fig.
113 3c, Supplementary Table 4). SST-derived thermal bias in natural communities had a small positive
114 effect on sensitivity, but this effect was lost when compared alongside vertical and horizontal gradients
115 in regression models (Supplementary Table 4, Model R1). Horizontal spatial gradients in surface
116 temperature had no effect on CTI sensitivity when considered with vertical gradients (Supplementary
117 Table 4).

118 Reduced CTI sensitivity to surface warming in areas of steep vertical temperature gradients is
119 consistent with a redistribution of species to greater depths²⁶. Such vertical gradients may allow

120 thermal niche tracking without horizontal shifts, and may provide refugia for cold-water species
121 without significant ecological consequences, unless limited to the surface by a need for light
122 (phytoplankton, coral, macroalgae), or habitat (intertidal organisms). The lack of influence of
123 horizontal thermal gradients on CTI sensitivity to surface temperature change suggests that horizontal
124 shifts in species distribution had comparatively little effect at the scale of the analysis ($2^\circ \times 2^\circ$ grids
125 over 30 years).

126 Patterns of observed CTI sensitivity matched expectations from simulations. More change in
127 community composition was seen in communities composed of species with greater diversity of
128 thermal affinities, narrower thermal ranges, and without access to refuges from climate change at
129 greater depths (i.e., outside areas of steep vertical temperature gradients where observed changes do not
130 match predictions). While negative thermal bias has been implicated as an indicator for community-
131 level vulnerability with warming¹⁷, we found instead instances of apparent negative SST-derived
132 thermal bias (e.g. demersal species in the Canadian Atlantic Maritimes: Fig. 3a) that were better
133 explained by vertical temperature gradients, with species' affinities closer to temperatures experienced
134 at depth than surface temperatures.

135 Studies of birds, butterflies and plant communities showing smaller changes in CTI than changes
136 in temperature have generally been interpreted as lags in response^{5, 9, 10, 11, 12}, but thermal range width
137 and community thermal range effects on CTI sensitivity may explain some of these apparent lags.
138 Short-lived plankton and species of highly mobile fish and invertebrates may be more responsive to
139 temperature change in time and space^{2, 6} than analogous communities on land, potentially as a
140 consequence of living closer to their thermal limits²⁷. Communities of long-lived, slowly dispersing
141 species may be less responsive in thermal affinity composition when increasing in abundance, but may
142 decline rapidly, as in the loss of cold-water kelp and influx of tropical fish in response to a recent

143 warming event in Western Australia²⁸. Slower-than-expected community responses may also be caused
144 by compensatory population dynamics²⁹ in individual species. Replacement of cooler-affinity species
145 by incoming warmer-affinity species is not possible in the tropics, likely resulting in the depression in
146 species richness at the equator³⁰. In addition, geographical barriers can also restrict routes for incoming
147 migrants, such as in the Mediterranean³¹, resulting in a lowered species turnover⁶ and capacity for CTI
148 change¹⁷.

149 Our study shows the dominant effects of recent temperature change on community turnover across
150 marine species from regional to ocean scales, regardless of other influences such as fishing impacts and
151 ocean acidification. The prediction of temperature effects at community scales derived from species
152 thermal performance curves³² provides a benchmark against which the pace of reorganization of global
153 biodiversity to climate can be judged, and allows assessment of the performance of quantitative
154 models^{3,4}. The predictability with which thermal diversity, average thermal range width and vertical
155 temperature gradients directly drive patterns of sensitivity of community composition to warming gives
156 a strong prognosis for the resilience of ocean communities to respond to climate change. In the
157 northern temperate coastal oceans in this study, warm-tolerant species of plankton and fishes are slowly
158 replacing their cold-tolerant counterparts over the timescales of climate change, and if those species
159 have similar roles, suggesting a capacity for the oceans to continue to function.

313 **and plankton communities from 1985 to 2014 influenced by near-surface vertical and horizontal**
314 **temperature gradients. a,** Thermal bias (CTI_{SST} - SST) versus vertical temperature gradient (lower
315 regression through demersal species, upper regression through plankton). **b,** Difference between
316 observed CTI trends and those predicted from surface temperature trends (Model B residuals) versus
317 local Community Thermal Diversity. **c,** Residuals from a regression including SST trends combined
318 with community thermal diversity, community thermal range (Model I residuals, mapped in **d**) versus
319 local vertical temperature difference. Error bars in **a-c** show bootstrap standard errors for CTI_{SST} trend
320 estimates. **e,** Vertical temperature gradients (0-50m, 1985-2014 from Hadley Centre EN4 dataset). **f,**
321 Relationships among CTI sensitivity, vertical and horizontal temperature gradients and thermal bias
322 shown by correlation (grey arrows, round parentheses) and regression beta coefficients (black arrows,
323 square parentheses) from regression of residuals from **b** (Supplementary Table 4 Model R1).

324

325 **Online only Methods**

326 **Simulation of sensitivity of the community temperature index to temperature change.**

327 Expected effects on the response of community thermal indices to temperature change were
328 explored in a simulation model based on species-level functions relating abundance to temperature.
329 Four functional forms were used: (i) Gaussian, with abundance declining symmetrically away from a
330 central optimum, (ii) a trimmed Gaussian, with a central plateau, and (iii) left- and right-skewed
331 functions based on the gamma distribution (Supplementary Fig. 1). Pools of 1000 species were created
332 by randomly selecting species' thermal midpoints (STI) from a Gaussian distribution with a mean of
333 15°C plus or minus an offset representing thermal bias¹⁷, the degree to which the community is
334 composed of types from warmer or colder conditions. Variation in thermal affinities in the species pool
335 was manipulated via the standard deviation of STI values in the species pool, (sdSTI, species pool
336 thermal diversity in Fig. 1e). Each species in the pool was assigned a thermal range (STR, species pool
337 thermal range in Fig. 1e), as the difference between the 90th and 10th percentiles of the abundance-
338 temperature function.

339 The four abundance-temperature functions (Supplementary Fig. 1) simulated different patterns of
340 abundance across species ranges. The Gaussian function represented species that are more abundant, or
341 occur in a greater proportion of samples, at the centre of the distribution range. In this form, the
342 equivalent standard deviation for a given STR (the difference between the 10th and 90th percentiles of
343 the distribution) was obtained by dividing STR by $2 \cdot t_{0.1, \infty}$ (the number of multiples of SD percentiles of
344 a Gaussian distribution). Simulated abundance (or incidence) of any species across the range of
345 temperatures considered, here 0°C to 30°C, was obtained from the probability density function of the
346 Gaussian distribution with the species' STI as the mean and SD-equivalent range width as its standard
347 deviation (as in Fig 1a-d). For the trimmed Gaussian function, simulated abundance between mean-SD

348 and mean+SD was set at the probability density value for the mean-SD and otherwise followed the
349 standard Gaussian formulation. For the skewed functions based on the gamma distribution, simulated
350 abundance was produced using the gamma probability density function for varying shape values, and
351 scale factors obtained by dividing the STR by the difference between the 90th and 10th percentiles of
352 each gamma distribution for the applicable shape value and a scale factor of 1.

353 Simulated abundance/incidence values were used to calculate Community Temperature Index
354 values (CTI, abundance-weighted average STI) and Community Thermal diversity (CTDiv, abundance-
355 weighted standard deviations of STI values) at different temperatures. The sensitivity of CTI to
356 temperature change (sCTI) was measured by calculating CTI for species at temperatures 0.1°C below
357 and above 15°C, and dividing the difference in CTI values by 0.2°C to give the ratio of CTI change to
358 temperature change.

359 We used linear regression analysis to analyse the response of CTI sensitivity (sCTI) to the
360 distribution of species thermal properties in these simulated communities. For the Gaussian abundance-
361 temperature function, CTI sensitivity exactly depended on the squared ratio of CTDiv to STR
362 (Supplementary Table 3, Model Z), with thermal bias having no meaningful effect. Adding variable
363 Species Thermal Ranges (Supplementary Table 3, Model Z1) reduced the sensitivity of CTI to
364 temperature at low levels of thermal diversity, but the effect was relatively small (Supplementary Table
365 5). With a flattened response of abundance to temperature emulated by the trimmed Gaussian function,
366 the negative effect of average species thermal range (CTR) was completely eliminated. Communities
367 composed of narrow- or wide-ranged species for the same level of thermal diversity had the same CTI
368 sensitivity (Supplementary Fig. 2b). This suggests that CTI metrics estimated from range information
369 alone would not be sensitive to the average range width of the species involved for this functional form.

370 For the asymmetrical abundance-temperature functions represented by the gamma and reversed
371 gamma functions (Supplementary Fig. 1), the effects of varying CTDiv, CTR and the shape of the
372 function were similar in both cases (Models Z3 and Z4, Supplementary Fig. 2c, 2e) but the effects of
373 thermal bias depended on the direction of the skew. For the right-skewed gamma distribution, CTI
374 sensitivity to temperature increased with thermal bias, producing a CTI that would change more rapidly
375 with temperature if composed of warmer-water species. The left-skewed reverse gamma abundance-
376 temperature function, with a shape more similar to physiological temperature performance curves,
377 showed the opposite effect, with more sensitivity of CTI to temperature if the community was
378 composed largely of species from colder waters. This behaviour suggests the rapid changes in
379 abundance at temperatures above the optimum produce more rapid shifts in CTI than the more gradual
380 changes in abundance below the optimum (Supplementary Fig. 1d). Notwithstanding such effects of
381 functional form of the abundance-temperature response on the sensitivity of CTI to temperature, the
382 observed patterns of abundance more closely followed the simple Gaussian function (see section:
383 **Average abundance and incidence across species thermal ranges**).

384 **Marine community data sources.**

385 Five marine community datasets were used (Supplementary Table 1). For analysis of patterns in
386 responses across spatially extensive time-series data, data from three bottom-trawl survey programs
387 and one plankton sampling program were downloaded and prepared such that every taxon record in
388 each sample (either a single trawl or section of Continuous Plankton Recorder silk) was associated with
389 a latitude, longitude and date. The three bottom-trawl surveys were organized into different regional
390 sampling programs, and data from each regional program were combined. US National Marine
391 Fisheries Service (NMFS) data were obtained from the Ocean Adapt website and pre-processed using
392 existing R code (Pinsky group, <https://github.com/pinskylab/OceanAdapt> downloaded February 2016).

393 European International Bottom Trawl Survey (IBTS) datasets were downloaded in a common format
394 with details of sizes of species caught and of each trawl, of which only the abundance, date and
395 location were used. Canadian Department of Fisheries and Oceans data came from the Ocean
396 Biogeographical Information System (OBIS) web portal, with similar details of sampling. Continuous
397 Plankton Recorder data were obtained directly from the Continuous Plankton Recorder Survey,
398 including date of hauls, longitude and latitude alongside estimated species abundance.

399 Each dataset recorded abundance in a different way but, for every dataset including those that
400 lacked abundance data, analyses were possible using species incidence among samples taken in the
401 aggregating location and period. Species incidence (the relative frequency of trawls in which the
402 species occurred, for data aggregated by area and time period) was used as the weighting factor in all
403 calculations of community thermal metrics (CTI, CTDiv, CTR), and was highly correlated with
404 abundance when available (Supplementary Fig. 10).

405 **Ocean temperature data.**

406 We used five sea-surface-temperature datasets and one layered subsurface dataset for analysis of
407 temperature change in the study region (Supplementary Table 1). Annual sea surface temperatures per
408 1° latitude-longitude grid cell were averaged over 1985 to 2014 for each dataset to represent long-term
409 climate over the period of surveys. Seabed temperatures were derived from the deepest layer in the
410 Hadley Centre EN4 dataset and averaged over the same period. Trends in °C/yr were calculated for 1°
411 cells using annual means from 1985 to 2014 (Fig. 2e, Supplementary Fig. 13). Vertical gradients in
412 temperature (Fig. 3d) were calculated using the EN4 dataset²⁵ from layer means (surface: 5.02m,
413 “50m”: 45.4m, “100m”: 98.3m, “200m”: 207.4m) based on annual means from 1985 to 2014 .

414 **Derivation of Species Temperature Indices (STIs) and fitted Maxent models.**

415 Global predicted distribution maps were produced using presence-only Maxent models for each
416 species in fish and plankton datasets occurring in ten or more 1° cells, and using default parameters for
417 a random seed, convergence threshold, maximum number of iterations, maximum background points
418 and the regularization parameter³ (Maxent version 3.3.3k). Observations of species presence from
419 OBIS were gridded such that 1° grid cells with observations were set as present. Only 2% of species
420 were found in <10 1°latitude/longitude gridcells, with most species found in 10 to 100 gridcells (10-32,
421 36%; 32-100, 37%; >100, 24%). These observations were then modelled as a function of the following
422 environmental predictors: (1) average annual temperatures from the HadISST v1.1; (2) the logarithm of
423 distance to the nearest coastline; (3) ocean depth from the GEBCO marine atlas; and (4) FAO major
424 fishing areas (<http://www.fao.org/fishery/area/search/en>). Frequency of all records in OBIS in 1° grid
425 cells was used as the bias correction file. Although we did not additionally spatially thin the input
426 records as has been suggested³³, the reduction of records to presence in 1° cells and inclusion of the
427 bias file were attempts to reduce spatial bias due to uneven sampling effort. Global maps of predicted
428 presence were produced using a threshold probability of 0.4, restricting the range of possible areas to
429 those of high suitability⁴.

430 Resulting Maxent-predicted distribution maps were used to extract sea temperature values from
431 long-term climatology average 1985-2014 from HadISST (henceforth CTIhadsst1), EN4 surface
432 (averaged across species to give CTIen4sst) and EN4 seabed (giving CTIen4sbt). Quantiles (0, 0.1,
433 0.25, 0.5, 0.75, 0.9 and 1.0, area-weighted by the cosine of the latitude) of these map-extracted
434 temperatures were used to define the thermal niche of the species. The 50th percentile (median) of
435 temperatures in occupied areas was used as the Species Temperature Index (STI, derived separately for
436 HadISST and EN4 SST and seabed). The difference between 10th and 90th percentile temperatures (T_{90}
437 – T_{10} , Fig. 1a) defined the Species Thermal Range (STR). A Species Temperature Index derived as the

438 average of T_{90} and T_{10} values obtained from species presence in 1° grid cells (giving CTI_{hadsst2} and
439 directly comparable to ¹⁷) was also used to compare analyses based on observation-derived thermal
440 affinities with analyses derived from modelled distributions (CTI_{hadsst1}).

441 Patterns in ocean temperature were used twice in the analysis: (i) as long-term mean values
442 matched to modelled species distributions to derive STIs and STRs, and (ii) as local trends over the 30-
443 year study period to compare with local trends in CTI values. Despite the use of information on sea
444 temperature more than once, information flows in the derivation of species thermal affinities and
445 analysis of spatial patterns were separate from those in the analysis of temporal patterns in community
446 thermal composition related to temperature trends (Supplementary Fig. 4). These separate pathways
447 allowed us to avoid circularity in reasoning.

448

449 **Average incidence (relative frequency of occurrence) across species thermal ranges.**

450 The form of the relationships of species incidence with range location was determined by first
451 matching species' incidence to local temperatures in 2° grid cells, and then locating those temperatures
452 relative to the thermal limits of the distribution of each species (Fig. 1b, Supplementary Fig. 3).
453 Average incidence values were calculated for every species in 2° latitude-longitude grid cells as the
454 frequency of samples in which the species occurred, expressed as a proportion of the total number of
455 samples across the whole period of each survey. Range location was derived from the average
456 temperature in the cell relative to range limits (Fig. 1b, T_{10} and T_{90} , equation in Supplementary Table
457 2).. Incidence values per 2° cell were rescaled for every species to give values relative to the average
458 incidence within the STR, so reducing the effect of prevalent species on the resulting pattern.
459 Percentiles (50%, 75%, 90%) of scaled-incidence values were then calculated in range-location unit
460 classes of $1/25$ from -2 to 2 (Fig. 1b, Supplementary Fig. 3). To check how well incidence reflected

461 species abundance, calculations were repeated for abundance measures where available (average
462 weight per trawl for NMFS data and number per haul for CPR and IBTS data) by summing numbers or
463 biomass and dividing this sum by the total number of samples in each 2° latitude-longitude grid cell
464 (Supplementary Fig. 3). Abundance changes across thermal ranges were calculated in the same way as
465 incidence changes.

466 **Community Temperature Index (CTI), Thermal Diversity (CTDiv), average Species Thermal**
467 **Range (CTR) and Thermal Bias in surveys.**

468 CTI values were calculated as incidence-weighted average STIs using data aggregated in 2° × 2°
469 areas to produce maps (Supplementary Figures 4 and 9), and temporal trends (Fig. 2). Community
470 thermal diversity, CTDiv, the spread of STI values around each CTI measure, was similarly calculated
471 as the incidence-weighted standard deviation of the STIs for species present in the grid cell or grid cell/
472 year combination. Community thermal range (CTR) was the incidence-weighted average of species'
473 STR values. Incidence (relative frequency of species in samples per aggregation unit) was used as the
474 weighting factor because abundance was expressed differently in each dataset (Supplementary Table
475 1): as total numbers per trawl sample (IBTS data), biomass per haul (NMFS data), and as scores per
476 silk (CPR data). However, incidence was strongly related to abundance in each set for which
477 abundance data were available (Supplementary Fig. 8). Thermal bias was calculated as the CTI minus
478 local sea temperature (using whichever temperature dataset was used to derive corresponding STIs),
479 giving positive values where more species were from warmer areas and negative values where the
480 species were from cooler places.

481 Uncertainty in CTI estimation is often poorly estimated³⁴ so, in addition to the four alternative
482 methods of derivation of STIs, we used bootstrap resampling of species to generate standard errors and
483 confidence intervals for means and trends in CTI and for the outcomes of more complex regression

484 analyses. Bootstrap sets of species were randomly selected with replacement from those in each survey
485 scheme (141 CPR, 285 IBTS, 585 NMFS, and 285 DFO species). The frequency of each species in the
486 bootstrap set was used as a multiplier on species incidence as the weighting factor (w_i in
487 Supplementary Table 2) to give bootstrap estimates of each of the community thermal metrics. Each
488 metric (annual mean, anomaly, trend) and regression model was computed for 500 repeated bootstrap
489 species selections, and summarised to give bootstrap averages, standard errors and 95% confidence
490 intervals.

491 For time-series analysis, the annual CTI values averaged per $2^\circ \times 2^\circ$ grid cell were expressed as an
492 anomaly from the 1985-2014 average CTI for that cell. US NMFS data had several regional series that
493 occurred together in the same grid cell, notably in the Northeast and Southeast US spring and fall
494 series. In this case, anomalies were calculated for each series separately then averaged to give final CTI
495 values for that cell. Trends in CTI for each $2^\circ \times 2^\circ$ cell were calculated using all years for which CTI
496 values were available, and matching trends for SST values were calculated for the same set of years.

497 **Uncertainty in annual CTI anomalies and temporal trends: data filtering**

498 The magnitude of CTI anomalies from long-term means in $2^\circ \times 2^\circ$ grid cells shows the effect of
499 sampling effort on the uncertainty in these estimates (Supplementary Fig. 11a, b). As expected, given
500 the standard error of the mean being proportional to the underlying standard deviation multiplied by the
501 square root of the sample size, the magnitude of anomalies declined with the number of species records
502 (STIs) used to compute each CTI value (Supplementary Fig. 11a). CTI anomalies were omitted from
503 trend analysis for bottom-trawl surveys if comprising fewer than 20 species records. Similarly, annual
504 CTI anomalies tended to be larger when composed of fewer bottom trawls or plankton samples.
505 Estimates based on fewer than 10 bottom trawls or plankton hauls per year were also excluded from
506 further analysis (Supplementary Fig. 11b).

507 Standard errors associated with trends in CTI over time in each $2^\circ \times 2^\circ$ grid cell were also related
508 to the number of years sampled and the total species records over the time series in each cell
509 (Supplementary Fig. 11c, d). Trends based on fewer than 10 years of data and less than 1000 species
510 records were omitted from further analysis.

511 **Analysis of trends in CTI versus community thermal traits: community thermal diversity**
512 **(CTDiv), average thermal range width (CTR) and thermal bias, and predictions of sensitivity**
513 **from simulated communities.**

514 Relationships between trends in Community Temperature Index (as bootstrap-mean CTI_{SST}) and
515 trends in sea temperature (HadISST), as modified by community thermal affinities, were analyzed by
516 fitting least-squares multiple linear regression models (Supplementary Table 4). The relative
517 importance of models was evaluated using Akaike weights. Intercepts were omitted from models
518 because no CTI change would be expected where the temperature trend was zero (unless there was
519 some delayed shift from an earlier period of warming or cooling). Adding intercepts back into these
520 models (Models A and Ci to Ni) had very little effect on model fits (as shown by $\Delta AICc$) or the
521 parameter value estimates, and did not result in intercepts that were significantly different from zero.

522 Terms were introduced first as linear effects and then as squared terms, reflecting the results from
523 the simulation model (Model Z). Modifying effects of average community thermal metrics (CTDiv,
524 CTR, Thermal bias) and local vertical and horizontal gradients in average temperature were expressed
525 as interactions with the temporal trend in sea surface temperature to address sensitivity of CTI to
526 temperature. Considering effects only as interaction terms reflected the assumption that change in
527 average thermal affinity would respond to changes in temperature, and that patterns of local average
528 thermal diversity, species range, or thermal bias would modify that change in CTI in response to
529 temperature. The model with the squared ratio of community thermal diversity (CTDiv) to species

530 thermal range (CTR, Model G) links the observational data with the simulation analysis. In simulations
531 using the Gaussian function, regression of log CTI sensitivity on log STR (=CTR in this case, since all
532 species in the simulation had the same STR) and CTDiv gave a perfect fit with coefficients of -2 and 2
533 respectively, which back transforms from logs to the one-parameter equation involving the squared
534 ratio of CTDiv to CTR (Model Z).

535 Adding the interactive effect of thermal diversity (CTDiv) to SST trend (dSST) produced a better
536 model (Model D vs B, $AIC_{cD} - AIC_{cB} = -63.90$), while adding thermal range (CTR) alone did not
537 (Model C vs B, $AIC_{cC} - AIC_{cB} = -2.52$). Including both factors, either as linear predictors (E) or
538 squared terms (F), further improved the model (Model E vs B, $AIC_{cE} - AIC_{cB} = -82.62$; Model F vs B,
539 $AIC_{cF} - AIC_{cB} = -77.03$). Thermal diversity was negatively correlated with inverse thermal range
540 width, resulting in large changes in parameter values when each factor was added to a model
541 containing the other. The squared-ratio model (CTDiv²:CTR²), Model G, equivalent to the model fitted
542 to simulation data (Z), had similar explanatory power to other models including those terms (E, F). The
543 parameter value for this model (G, 7.63) was close to the 6.54 obtained for simulated communities (Z).

544 Thermal bias affected CTI sensitivity in the simulations, negatively or positively depending on the
545 direction of skew of the abundance-temperature relationship, and so was introduced as an addition to
546 the squared ratio model. Adding thermal bias slightly improved model fit (Model H vs G, $AIC_{cH} -$
547 $AIC_{cG} = -1.18$) and increased the sensitivity of CTI by 0.04 for each °C of thermal bias. This positive
548 effect meant that communities comprising warm-water species showed greater change in CTI than
549 those composed of cold-water species for the same change in temperature. The effect was also
550 consistent with the effect of realized right-skewed (gamma) abundance-temperature distribution in the
551 simulations, but not a left-skewed one as implied by typical physiological thermal performance
552 curves³⁵.

553 Both horizontal and vertical gradients in temperature were expected to influence CTI sensitivity.
554 Steep vertical gradients in temperature may have a negative effect on CTI sensitivity because species
555 may be able to shift to cooler temperatures in the same area by moving deeper. Gentle horizontal
556 gradients in temperature, combined with temperature change through time, result in higher velocities of
557 climate and thereby more rapid distribution shifts among species^{2, 18}. With a greater rate of species
558 turnover in areas of high climate velocity, we expected a negative relationship between CTI sensitivity
559 and the magnitude of the horizontal gradient in temperature. Adding shallow vertical temperature
560 differences (surface less 50m) improved the model with community thermal diversity and thermal
561 range (Model I vs G, $AICc_I - AICc_G = -33.39$), albeit with no effect of vertical differences from surface
562 to 100m (Model J) or 200m depth (Model K). Adding horizontal temperature gradient (Model L) to the
563 basic model (G) had a smaller effect on model fit ($AICc_L - AICc_G = -3.15$) and did show the expected
564 negative influence of the horizontal gradient. Combining vertical and horizontal gradients in
565 temperature (Model M) did not improve model fit, and the horizontal gradient coefficient did not differ
566 from zero. A regression model that included thermal bias effects as well as horizontal and vertical
567 gradients in temperature (Model N) was the most parsimonious, albeit with the parameter for horizontal
568 gradient not significantly different from zero. Residuals from the squared-ratio model proved to be
569 related most strongly to the effect of vertical temperature gradient (Model R1, Fig. 3b).

570 Cross validation of was used to examine the predictive skill of Model I (Supplementary Table 4,
571 Supplementary Fig. 12). We used dataset type (bottom trawls or plankton) and latitude and longitude
572 (giving contiguous spatial blocks) to split the data into near similar-sized training and test datasets, with
573 each set alternately used as the training set for the other test set of data. Choices of splits for latitude
574 (50°N) and longitude (40°W) were arbitrary, but adopted to produce adequately sized datasets for
575 fitting. Model I fitted to the plankton subset as training data (Model Icpr) and bottom-trawl subsets
576 (Model Idem) produced similar parameter estimates (significant $P < 0.05$), with CTI trends for bottom

577 trawls explained markedly better. Splitting into plankton and demersal species gave the worst fits to the
578 other as test data (CV rsme 0.0284), the plankton training set predicting larger CTI trends than the
579 bottom-trawl training set. Splitting by latitude and longitude gave similar root mean squared errors to
580 the plankton / bottom-trawl split (Supplementary Table 4), but produced non-significant parameter
581 estimates for the vertical temperature gradient term for data west of 40°W. Model residuals for Model I
582 showed some spatial structure (Supplementary Fig. 12a), with evidence for spatial autocorrelation in
583 the CTI trends and in the predictor variables (Supplementary Fig. 12b-c).

584 Of all predictors tested beyond the effects of thermal diversity and thermal range, the vertical
585 temperature gradient effect had the largest influence on CTI sensitivity, (Fig. 3f). The apparent positive
586 effect of thermal bias was due to the negative association with vertical gradient for demersal species
587 (Fig. 3a), and the small negative effect of horizontal gradient was due to the weak positive association
588 of vertical and horizontal gradients of temperature, particularly in the northwest Atlantic.

589 **Evaluation of explanatory power of alternate sea temperature datasets in explaining spatial** 590 **variation in trends in CTI anomalies**

591 We fitted a subset of regression models in Supplementary Table 4 to every combination of four
592 variants of CTI and temperature trends from nine dataset layers: five surface layers (EN4SST,
593 COBESST, ERSST, HadISST and OISST, Supplementary Fig. 13) and four subsurface layers
594 (EN4SBT, EN4 50m depth, EN4 100m depth and EN4 200m depth). Models were fitted for every
595 bootstrap selection of species (n=500), with model fits and 95% bootstrap confidence intervals shown
596 in Supplementary Fig. 14. The most variation in CTI was explained for CTI_{SST} from STIs obtained by
597 matching modelled species distributions to surface temperature (aCTI_{en4sst} and aCTI_{hadsst1}), with the
598 poorest performance of models fitted to CTI_{SST} from STIs obtained by matching 1° mapped
599 observations of species presence in gridcells (from OBIS data summed for the period 1960 to 2009) to

600 surface temperatures (aCTI_{hadsst2}). Trends in seabed temperatures did least well in terms of adjusted
601 R² at predicting CTI_{SBT} or CTI_{SST}. Models that included terms for the squared ratio of thermal diversity
602 to range width fitted better when in combination with magnitude of vertical gradient and/or horizontal
603 gradient.

604 **Data availability**

605 The data that support the findings of this study are available at the publicly accessible repositories
606 listed in Supplementary Table 1. The Community Temperature Index (CTI) values and species thermal
607 affinity data that support the findings of this study are available as annual values and 30 year means³⁶
608 (Supplementary Fig. 7) and as trends³⁷ in 2° × 2° grid cells (Figs 2, 3, Supplementary Fig. 5). Species
609 thermal affinities derived from models and observations are also available³⁸. Source data for the
610 analyses presented are available at links given in the supplementary information files. Source code for
611 the simulation of CTI response to temperature change is available at
612 <https://github.com/michaeltburrows/ctisimulation> (Fig. 1).
