Running title: Genetic diversity in fragmented populations

Keywords: agent-based model; individual-based model; genetic diversity; individual recognition; mate choice; population fragmentation; sexual selection; dispersal

Acknowledgments: Thanks to Chris Thomas, Michael Bottery, Jacob Davis and Miguel Franco for comments on the draft manuscript.

22 **Abstract**

23 Many species advertise their unique identity to conspecifics using dedicated individuality
24 signals: one familiar example is human faces. But how unique in the global population do
25 these signals need to be? While human faces are highly variable, each person interacts with
26 many fewer individuals than are found in the total population. This raises the question of
27 how evolutionary mechanisms drive up population-wide diversity when selection occurs at
28 such a local level. We use an individual-based model in which individuals broadcast their
29 identity and quality in separate, genetically-coded signals. Mimicking, for example, scent
30 marking mammal species, females in the model assess males using the quality signal, then
31 attempt to relocate the highest quality male using his identity signal. We ask how
32 population fragmentation affects genetic diversity in the individual identity-signalling region
33 under sexual selection, predicting one of two opposing outcomes: (1) divided populations
34 evolve fewer signal variants globally, since repetition of signals is not costly when individuals
35 interact only with local conspecifics, or (2) stochasticity in mutation and selection cause
36 divergence among subpopulations, increasing the global number of signal variants. We
37 show that local selection drives up global genetic diversity substantially in fragmented
38 populations, even with extremely low rates of dispersal. Because new signal variants arise
39 by mutation and then sweep through their subpopulation, a fragmented population has
40 more global signal variation. This result furthers our understanding of how high levels of
41 diversity in individuality signals are maintained.

42

43 **Introduction**

44 Individual recognition – the ability to identify conspecifics to the level of the individual –
45 appears to be a widespread ability in species from a broad range of taxonomic groups (e.g.
46 humans: (Sheehan and Nachman 2014), wasps: (Sheehan and Tibbetts 2010), mice: (Hurst
47 et al. 2001), lobsters: (Karavanich and Atema 1998), birds: (Medvin et al. 1993)). Across
48 these groups, individuals benefit from being recognized because accurate recognition
49 carries fitness benefits: these include the maintenance of complex social hierarchies
50 (Tibbetts 2002), facilitating mate choice (Aquiloni and Gherardi 2010, Cheetham et al. 2007),
51 ensuring accurate provision of parental care (Jouventin and Aubin 2002) and recognition of
52 neighbouring territory holders (Hurst et al. 2005) or colony mates (Sheehan and Tibbetts
53 2009). Where benefits to the signaller exist, we expect selection to drive the evolution of
54 individuality signals (Johnstone 1997, Tibbetts and Dale 2007) through negative frequency-
55 dependent selection on rare signal types (Dale et al. 2001). Human faces are a probable
56 example of individuality signalling diversity that has arisen under selection for rarity
57 (Sheehan and Nachman 2014).

58 While there is evidence that complex social interactions can drive the evolution of diversity
59 in identity signals (Tibbetts and Dale 2007), little is known about how much variability
60 evolves in different systems. There are good reasons to expect that not every individual in a
61 population needs to have a unique identifier. While human faces, for example, appear to
62 offer an almost unlimited number of unique variants, and show little overlap within
63 populations (Sheehan and Nachman 2014), individual recognition may still be beneficial
64 even when there is some overlap among individuals' identity signals (Dale et al. 2001). Some
65 identification errors might be acceptable, and, even in humans, receivers are often confused

66 by similar-looking faces (Tibbetts and Dale 2007). Curiously, Tibbetts and Dale (2007)
67 inadvertently emphasize this point by making just such an error, mislabelling two of the five
68 pictured human faces in their figure legend. So, acceptability of occasional identification
69 errors means that not every individual needs to be globally unique. Second, we might also
70 find shared signals in the population as a consequence of limits to the combinatorial
71 diversity available in the signalling system (e.g. because it is coded by a single locus). Finally,
72 some degree of signal sharing might be expected to evolve because in most cases an
73 individual interacts with only a small proportion of the total population. For instance, there
74 appear to be vastly more human faces than are required for day-to-day human interactions,
75 meaning combinatorial diversity in faces far exceeds what is needed to maintain social
76 processes.

77 While there are several reasons to expect some degree of signal sharing, we predict a
78 relationship between the number of interacting individuals and the number of signals that
79 evolve. Where dispersal is high, or populations are large, more signal variants will be
80 required to ensure misidentification is rare. Indeed, positive correlations between group
81 size and signal diversity have been reported in bats (Luo et al. 2017) and chickadees
82 (Freeberg 2006), and there is evidence that species-level signal variability is linked with
83 coloniality in swallows (Medvin et al. 1993). There may be a threshold population size
84 beyond which individual identity signals do not evolve, either because of the difficulties of
85 recognizing large numbers of individuals, or because of group instability (Rohwer 1982).
86 However, beyond these few studies, there is little theoretical analysis of how group size
87 might affect the evolution of signal diversity. In particular, the relationship between the
88 number of signals found within each interacting group and the total signal diversity in the

89 population, has not been explored. Understanding the dynamics of this relationship should
90 help explain why, for example, most humans interact regularly with only ~150 individuals
91 (Dunbar 1992) and yet there are billions of apparently unique human faces on the planet.

92 Here we explore the effect of interacting group size on the evolution of individuality signals
93 using an agent-based model of a population subject to different levels of fragmentation. We
94 previously used this technique to show that variation in individual identity signals can arise
95 as a consequence of even very weak sexual selection on male attractiveness (Thom and
96 Dytham 2012). The model simulates a species in which females encounter male quality and
97 identity information in two separately encoded signals that are temporally separated from
98 the signaller. Females subsequently encounter the males and can correctly identify and
99 mate with the highest quality individual only if his identity signal is unique – if it is not, they
100 choose randomly from the males that share the signal. This temporal separation between
101 assessment and mating mimics the mate choice mechanisms found in species that leave
102 scent marks in the environment (Cheetham et al. 2007), broadcast auditory signals (Seddon
103 and Tobias 2010), or in which females observe male contests and subsequently mate with
104 the winner (Aquiloni and Gherardi 2010). Similarly, physical displays of attractiveness in
105 humans – such as ritual jumping by Maasai men (Fink et al. 2019) – are often temporally
106 distinct from subsequent mate choice events in which the chooser recognizes the ‘best’
107 male from the earlier display.

108 We predicted that either of two opposing outcomes could emerge from subdivision of the
109 population into patches. First, because the benefits of signal uniqueness are related
110 primarily to local diversity in a fragmented population, signal overlap between patches
111 might not be strongly selected against and each individual signal might be repeated

112 numerous times at the global scale, thereby reducing global signal variation. Alternatively,
113 because the evolutionary trajectory of each patch is largely determined by the local effects
114 of drift and mutation, global signal diversity might exceed that found in a well-mixed
115 population. We find that sexual selection can maintain local (within-patch) diversity in
116 signalling loci even when the population is highly fragmented. Significantly, summing the
117 signal variants across all patches reveals that population fragmentation increases the global
118 signal diversity by 10 – 15% above that found in non-fragmented populations, revealing a
119 substantial genetic diversity dividend to population subdivision.

120

121

122 **Methods**

123 We use an individual-based model of a sexual population with discrete events following
124 Allen & Dytham's (2009) adaptation of the Gillespie (1977) algorithm for simulating
125 continuous time models. Extending the single, well-mixed population approach of Thom &
126 Dytham (2012), we model a one dimensional ring of discrete patches connected by
127 dispersal. An event can be either a birth (with possible dispersal to an adjacent population)
128 or a death, and time advances after each event. The probability of a death event is density
129 dependent and the population size will show stochastic logistic growth. We use an
130 equilibrium density of 10,000 individuals divided equally across identical patches. The
131 number of patches varies from 1 to 50, so the population ranges from 1 patch with 10,000
132 equilibrium density, to 2 patches with 5,000 through to 50 patches with an equilibrium
133 density of 200.

134 Each individual carries a diploid attractiveness locus with alleles that can take any value, and
135 six unlinked, diploid loci with four possible alleles at each locus. We consider the loci in two
136 groups of three. One group controls signalling and the other evolves neutrally under
137 mutation and drift only. There are 1000 possible unique combinations in each group (10
138 unique combinations at each locus, because genotype AB is phenotypically equivalent to
139 BA), and thus 10^3 (1000) possible individuality signals.

140 A random individual is chosen from the global population of N individuals and an event type
141 (either birth or death) is chosen at random. Time moves on an average of $1/2N$ of a time
142 step after each event. If birth is selected and the chosen individual is female, she chooses a
143 mate from a random selection of 10 individuals from within the same patch. The focal
144 female either selects a male on attractiveness criteria (see below) or is assigned one at

145 random, with a probability of 0.5 for each. If no males are encountered there is no birth, but
146 if a male is encountered then the female produces a single offspring. At birth, the new
147 individual is randomly assigned a sex (even sex ratio), inherits one allele for each of the six
148 marker loci from each parent, and one attractiveness allele from each parent. There is no
149 linkage. There is an independent chance of mutation for marker and attractiveness alleles.
150 For signalling or neutral region mutations, there is a 1:1000 chance that one allele of 12 will
151 mutate to one of the three different states. This represents a 1:6000 mutation rate per
152 locus, which is of the order used in other simulation models (Roff 1998). Our mutation rate
153 of 1:500 per locus for attractiveness is substantially higher because we assume that
154 attractiveness is the product of numerous alleles across the genome, and thus that the
155 mutational target is relatively large (Hunt et al. 2004). When an attractiveness allele
156 mutates, a random number from a normal distribution with a mean of -0.02 and standard
157 deviation of 0.02 is added to the existing allele with the result that the majority of mutations
158 have negative effects on attractiveness. Following Thom & Dytham (2012), there is no upper
159 limit on attractiveness. After birth the individual has a probability, set by the dispersal rate,
160 of moving to an adjacent patch. Patches are arranged in a ring, and dispersal in a clockwise
161 or anti-clockwise direction is equally likely. We use dispersal rates of 0, 0.0001, 0.001, 0.01,
162 0.1 and 0.5. Individuals have no more than one dispersal event during their lifetime.

163 We used a discrimination rate of 50% for simulations here, based on previous simulations of
164 this system (Thom and Dytham 2012) — females choose the best male in half their mating
165 opportunities; the rest of the time, they select randomly from males they have
166 encountered. When discriminating, a female chooses a mate based on male attractiveness
167 using the sum of the two attractiveness alleles. The female rejects all males that have

168 signalling loci different from those of the most attractive male, and then chooses a mate at
169 random from those remaining. There is no other effect of attractiveness or signalling on
170 fecundity, dispersal or mortality, and females assess male attractiveness without error.

171 Populations are initiated with the number of individuals equal to the equilibrium density
172 (10,000) spread randomly across patches. At initiation, each individual has an equal chance
173 of being male or female. All markers are set to the same value (i.e., there is initially no
174 variation in signalling or neutral loci) and each attractiveness allele is assigned a random
175 value drawn from a uniform distribution between 0 and 1. We describe a “time step” as the
176 period when the number of possible events is twice the population size. We used 100
177 realisations for each parameter set tested (the ‘neutral’ model, with female discrimination
178 rate set to 0, was replicated 40 times). Simulations ran for 50,000 time steps, by which time
179 population dynamics had settled into an equilibrium state.

180 Statistical models were performed using data from the end of the model run. We collected
181 data on signal diversity at two scales – global and local. Global signal diversity is the total
182 number of signal variants found in the entire population, and local signal diversity is the
183 mean number of signal variants in each patch. Effect sizes for local signal diversity are thus
184 the mean of means, as we used each model replicate as a statistical replicate in analyses. To
185 test the effect of increasing levels of fragmentation on signal variability, we conducted linear
186 models with signal number (either global or local) as the response variable and the number
187 of patches in the system as a factor – these analyses were performed pairwise, with each
188 level of fragmentation compared to both (a) the panmictic one-patch system and (b) the
189 next level of fragmentation to identify any threshold where increasing population
190 subdivision ceased to have any effect. To assess whether the sexual selection mechanism

191 was specifically driving up variation in the identity signalling system we compared the
192 number of signal and neutral variants at the end of the model run using paired T tests. All
193 analyses were performed in R version 3.3.2 (R Core Team 2017).

194 **Results**

195 Because the number of signals within a patch is limited by the number of individuals
196 available to carry them, within-patch signal number is lower than in the panmictic system
197 (across dispersal rates; all $F_{1,198} > 19.2$, all $p \ll 0.001$), as it is in the non-signalling regions
198 invisible to selection (all $F_{1,198} > 5.0$, all $p < 0.027$ except 2 patches vs 1 patch at dispersal of
199 0.1 [$F_{1,198} = 2.0$, $p = 0.154$] and 0.5 [$F_{1,198} = 2.9$, $p = 0.093$]; Figure 1). However, signalling loci,
200 which are under selection through female choice, retained higher levels of variation than
201 non-signalling loci at all levels of fragmentation and dispersal (paired t-tests, all $t_{99} > 15.2$, all
202 $p \ll 0.001$), even in the most conservative case of the 50-patch system and no dispersal
203 (mean \pm SE signalling variants per patch = 3.1 ± 0.04 ; non-signalling variants per patch = 2.0
204 ± 0.02 ; paired t-test $t_{99} = 26.2$, $p \ll 0.001$). Thus, sexual selection maintains positive
205 selection on male signal rarity even when local population size is small and dispersal is
206 extremely rare (see also Figure S1). We confirmed the expected isolation-by-distance in F_{ST}
207 values between pairs of patches (Figure S2). Tracking the spread of signals in a single
208 replicate confirmed that genetic diversity was maintained by negative frequency
209 dependence, ensuring that the number of signals present in the population remains diverse
210 over time (Figure S3). By contrast, in the non-signalling region of the genome invisible to
211 selection, drift leads to rapid changes in the frequency of the most abundant genotype, and
212 in relatively small numbers of genotypes dominate in the population at any time.

213 The effects of fragmentation on evolutionary diversity across a species can be understood
214 by investigating the global (population-wide) number of signal variants under different
215 regimes. Global diversity in the signalling region remained significantly higher than genetic
216 diversity of the neutral region across all dispersal and fragmentation levels (all $t_{99} > 14.3$, all p
217 < 0.001), demonstrating that population fragmentation does not break down the
218 mechanism of sexual selection maintaining signal diversity at a global scale. Even more
219 strikingly, at low to intermediate dispersal rates, the number of global signal variants
220 significantly increased at intermediate levels of fragmentation compared to the levels of
221 diversity seen in the single-patch system (Figure 1, hollow arrowheads). At the lowest non-
222 zero dispersal rate of 0.0001, the global number of signal variants peaked at a value 10%
223 higher than that found in the single patch system. At 0.001, 0.01 and 0.1 dispersal rates the
224 peak was 13-15% higher than in a single patch system (all $F_{1,198} > 13.8$, all $p < 0.001$).
225 Population fragmentation was associated with lower global signal variation only in the
226 absence of dispersal (Figure 1, top axis rug).

227

228 **Discussion**

229 Even when populations become highly fragmented and subpopulation size is small, female
230 choice of males they individually recognize can drive the evolution of genetic diversity in the
231 signalling region. Indeed, fragmentation drives genetic variation in the population
232 substantially above that of unfragmented populations, suggesting a potentially important
233 role for population subdivision in maintaining evolutionary diversity.

234 In subpopulations as small as 200 individuals, sexual selection on male quality drives
235 genetically-coded signal diversity higher than that found in an equivalent neutral genome
236 region. Although the mechanism of selection modelled here is relatively weak – in only 50%
237 of matings do females even attempt to discriminate the best male, and they investigate only
238 10 individuals before choosing – it was sufficiently effective to counteract the loss of allelic
239 diversity through drift and to increase signal diversity across a range of demographic
240 conditions (dispersal and local population size). We conclude that the evolution of individual
241 variation, at least under this mechanism, does not appear to be prevented by small local
242 population sizes. In small populations we find that the absolute number of signal variants is
243 low: in the case with no dispersal and 50 patches there were only 3.1 signal variants per
244 patch, meaning 65 individuals in each patch shared the same signal on average. Even at this
245 high level of signal sharing, the mechanism of selection we describe here drives the
246 evolution of greater signal diversity in signalling than non-signalling regions. In more
247 biologically-plausible, intermediate parameter sets we see much lower rates of signal
248 sharing (e.g. at 50 patches and dispersal of 0.1, there are 90 signal variants and just 2.2
249 individuals on average with each signal variant). While the number of signals in any
250 population is constrained by either the number of carriers or the total combinatorial

251 diversity available from the signalling system, we have shown that selection can maintain
252 variation in both local and global signal numbers across a large range of population
253 fragmentation levels. Sexual selection is thus a robust mechanism for the evolution of
254 individuality signals.

255 More importantly, we find that global signal diversity is dramatically enhanced when the
256 population is subdivided. This contradicts our expectation that the rescue of rare alleles by
257 negative frequency dependence would be most effective in a panmictic population. Instead,
258 global signal diversity is elevated by population fragmentation by three mechanisms. First,
259 in a subdivided population there are many 'best' males (as many as there are patches), and
260 that the absolute quality required to be the local best is lower when the population is more
261 subdivided. Second, with many 'best' males the likelihood of a high-quality male also
262 carrying a rare signal variant is improved (since 1000 signal variants are possible in our
263 system, but in the most subdivided population there are only 200 individuals), giving more
264 opportunities for the selection mechanism to gain traction. Finally, in a subdivided
265 population any relatively high-quality individual that disperses will be more likely to possess
266 a rare signal variant in the destination population, increasing its chances of spreading
267 through selection on rarity and quality.

268 There are a number of examples of signal characteristics varying with geography, including
269 in chimpanzee calls (Mitani et al. 1999), in major urinary protein expression among
270 subspecies of house mice (Hurst et al. 2017, Sheehan et al. 2019), in human faces (Guo et al.
271 2014), and in intraspecific bird song dialects (Baker and Cunningham 1985). While this
272 geographic diversity can develop under a number of processes, our model predicts such
273 variation in fragmented populations of species in which there is temporal separation of

274 mate assessment and mating. One such system in which this hypothesis might be tested in
275 the future is in birds, where our data suggest that lekking species might avoid the negative
276 genetic diversity effects of fragmentation: there is indeed some evidence that lekking
277 grouse do not always suffer the expected decline in genetic diversity with population
278 fragmentation (Bush et al. 2011, Segelbacher et al. 2008). Thus our model describes a
279 mechanism for understanding of the paradox in which lek mating species maintain higher
280 than expected genetic diversity in the face of sexual selection (Kotiaho et al. 2007).
281 Counterintuitively, our result suggests that fragmentation may in fact elevate genetic
282 diversity in such a system, at least in signalling regions and among linked loci.

283 The rate of dispersal has substantial effects on patterns of genetic diversity in our model, as
284 it does in fragmented wild populations (Riginos et al. 2014). With no dispersal we see the
285 effects of drift vs. mutation and frequency dependence, and global signal diversity is not
286 enhanced by population fragmentation. With a high dispersal rate the system behaves as a
287 single, panmictic population. At intermediate dispersal, signals that are attached to high
288 quality males increase in frequency, and thus increase their probability of spilling over into
289 adjacent populations where the strength of positive selection will increase. Interestingly,
290 there were quite striking effects of both dispersal and fragmentation on mean population
291 quality (which was uncapped): the lowest rates of quality evolution were in the most
292 fragmented populations with low dispersal, the highest rates in relatively unfragmented
293 populations with high dispersal (approaching a panmictic system). This matches the
294 prediction that selection should operate more effectively in larger populations where the
295 impact of drift is reduced.

296 One counteracting pressure that we expect to see is “impersonation”, where an individual
297 with low attractiveness, but whose individuality signal matches that of a high-quality male,
298 gains ‘unearned’ reproductive output. Because females choose at random from within the
299 pool of males that carries the best male’s signal, unattractive males are only likely to obtain
300 matings from discriminating females if they are in this pool. This kind of identification error
301 did happen in our system, although ‘unearned’ reproductive success was rare (< 10% of
302 matings) except in very fragmented populations with very low dispersal rates (Figure S4).
303 This type of mimicry might be particularly likely to occur in systems that allow some signal
304 plasticity (e.g. vocalizations: Hile et al. 2000). In our model, the most likely cost of
305 inadvertent signal copying is that when an impersonated signal spills out into neighbouring
306 patches the mean quality of the dispersers will be lower because of the imposter, and the
307 spread will thus be weaker than it would be in the absence of impersonation. Of course, the
308 risk of impersonation would be reduced with a larger signal set – we allowed 1000 signal
309 variants, but this may be rather conservative compared to the number available with more
310 loci or alleles contributing to the signal, or if there is variation not only in genotype but also
311 in relative expression (e.g. Sheehan et al. 2016).

312 While our model simulates the type of social environment described by Sheehan & Bergman
313 (2016), where an animal moves from one social group to another, the system described
314 here does not require the accumulation of specific information about individuals following
315 repeated encounters, since the female assesses quality and ‘memorizes’ matching
316 individuality information simultaneously. The model operates purely through a series of
317 instantaneous mate choice decisions by females. Much more complex mechanisms than this
318 undoubtedly occur in species with complex social systems where repeated encounters and

319 memorization of individual-specific traits are an alternative mechanism explaining the
320 evolution of individual recognition (Tibbetts and Dale 2007).

321 Previous studies of individual recognition have identified this process as an
322 underappreciated mechanism for maintaining polymorphism (Sheehan and Tibbetts 2010).
323 However, there has been little exploration – or even reporting – of the effects of individual
324 recognition on species-wide genetic variation. Here we show that population fragmentation
325 drives up global variation in signalling regions by between 10 and 15% above that expected
326 in a non-fragmented system even when only half of the females are discriminating. This
327 finding contrasts with the many examples in which habitat fragmentation is bad for diversity
328 (Hanski 2015). Although the idea that physically isolated populations undergo separate
329 evolutionary trajectories is not in itself surprising, the strength of the effect we demonstrate
330 here, and the degree to which selection has an effect even in very small subpopulations, are
331 potentially significant for conservation. This would particularly be the case if genetic
332 diversity in non-signalling regions piggybacked on this increased diversity through, for
333 example, linkage. Our result thus adds to the evidence for positive effects of habitat
334 fragmentation on biodiversity (Fahrig 2003, Fahrig 2017, Fahrig et al. 2019).

440

441

442 **Figure 1.**

443 Global number of genotypes (red symbols) and mean genotypes per patch (blue symbols)
444 across a range of levels of population fragmentation (x-axis) at the end of the model run.
445 Large symbols: genotypes visible to females and evolving under sexual selection; small
446 symbols: genotypes invisible to females and evolving only under neutral processes. Data are
447 means from 100 replicate model runs with standard deviations. The number of patches in
448 the global population is shown on the x-axis, with six rates of dispersal between patches on
449 separate panels. Both globally and locally, genotypes visible to selection had significantly
450 higher numbers of variants than genotypes invisible to selection at all levels of
451 fragmentation and dispersal. Note that for the single-patch system, global and local
452 genotype variability are necessarily identical. The top axis rug (red ticks) marks levels of
453 fragmentation at which global signal diversity is significantly different from signal diversity in
454 the single-patch system; maximum global signal diversity for each dispersal rate is marked
455 with an arrow. Because local signal diversity at all levels of fragmentation was significantly
456 different from signal diversity in the single-patch system, the x-axis rug (blue ticks) instead
457 marks points at which local signal diversity is significantly different ($p < 0.05$) from local
458 signal diversity at the immediately preceding level of fragmentation. Rugs were calculated
459 using linear models with number of genotypes as the response variable and number of
460 patches (restricted to the two levels of interest) as a factor.
