The influence of mantle hydration and flexure on slab seismicity in the southern Central Andes

Constanza Rodriguez Piceda^{1,2,3✉}, Ya-Jian Gao^{1,4,5}, Mauro Cacace¹, Magdalena Scheck-Wenderoth^{1,6}, Judith Bott¹, Manfred Strecker² & Frederik Tilmann^{1,4}

Knowledge of the causative dynamics of earthquakes along subduction-zone interfaces and within oceanic slabs is relevant for improving future seismic hazard assessments. Here, we combine the analysis of seismic tomography, the 3D structure of the slab and seismicity to investigate the controlling factors driving slab seismic activity beneath the southern Central Andes. We evaluate the ratio distribution between compressional and shear-wave seismic velocities (V_p/V_s) as a proxy for the hydration state of the lithospheric mantle, oceanic slab, and plate interface. Regions of high V_p/V_s , i.e. areas of hydrated mantle, are principally caused by compaction effects and dehydration reactions. In contrast, slab seismicity in areas of low V_p/V_s and inferred lower fluid content in the overriding plate is facilitated by enhanced flexural stresses due to changes in the subduction angle of the oceanic plate. Plate-interface background seismicity correlates with areas of higher V_p/V_s (hydrous interface) at depths <50 km, while areas of most pronounced plate-locking coincide with regions of low V_p/V_s (anhydrous interface). The regions of anhydrous plate interface are likely candidates for future great megathrust events due to their higher potential for elastic energy accumulation compared to more hydrated regions.

In subduction zones, slab seismicity along the megathrust interface (inter-plate seismicity) and within the oceanic crust and mantle (intra-slab seismicity) represents one of the sources of the greatest seismic hazards on Earth. An understanding of the causative mechanisms behind the spatial distribution of these earthquakes (e.g. extent of the seismogenic zone) allows an improved evaluation of the seismic hazard in these convergent settings. Thermomechanical modelling in various tectonic settings, including rifts, and transform and convergent margins^{1–3}, has shown how the long-term mechanical strength of the lithosphere may control the distribution of seismicity, with the brittle-ductile transition (BDT) generally identified as the downdip limit to the seismogenic zone^{4,5}. However, oceanic plates in subduction zones generate seismicity at depths greater than 50 km, where lithostatic pressure and temperature conditions should tend to inhibit brittle failure^{6,7}. In recent years, a growing number of studies has discussed the role of weakening due to fluids released during dehydration processes in the oceanic plate as the cause for such intermediate-depth earthquakes (50–300 km)^{8–11}. While the exact physical mechanism is still a matter of debate, the main processes proposed to enable brittle faulting under hydrated conditions include dehydration embrittlement^{8–10} and dehydration-related stress transfer¹¹. However, geological observations from fossil subduction zones¹² and from rock mechanics experiments¹³ have shown that brittle failure causing intermediate-depth earthquakes can also occur under dry conditions. Thermal runaway slip weakening¹⁴ provides a plausible mechanism to explain their occurrence.

Irrespective of the exact physical process involved, seismicity is triggered in response to the build-up and distribution of stresses in the slab. These reflect a balance between multiple forces, including buoyancy forces associated with thermal and metamorphic density contrasts, frictional resistance along the subduction interface and slab, and flexural stresses related to changes in the subduction angle^{8,9,15–17}. Quantifying the relative importance of dehydration mechanisms and slab stress in triggering slab seismicity requires a comprehensive integration of available geological, seismological, and geodetic observations.

The convergent margin of the southern Central Andes (29°S–39°S), where the oceanic Nazca Plate subducts under the continental South American Plate, is a subduction environment where a high number of great earthquakes have been recorded (e.g. 2010 M8.8 Maule and 2015 M8.2 Illapel)^{18,19}. A distinctive feature of this region is the change in the subduction angle of the Nazca Plate between 33°S and 35°S from the Chilean-Pampean flat-slab zone (<5° dip, 27–33°S) in the north to a steeper segment in the south (~30° dip)²⁰ (Fig. 1a). Domains with the highest frequency of slab seismicity²¹ are associated with the oceanic slab subducting sub-horizontally or with a shallow dip. These domains are located either close to the trench or along the flat-slab segment, below the Andean Precordillera fold-and-thrust belt and the thick-skinned Sierras Pampeanas morphotectonic provinces (Fig. 1b).

In the southern Central Andes, a recent thermo-mechanical modelling study²² constrained the downdip extent of the brittle-ductile transition to 40–55 km depth (Supplementary Fig. 1), thus implying that the spatial distribution of slab seismicity at depths <50 km is expected from variations in the long-term strength of the lithosphere. However, seismicity also occurs at depths >50–70 km, where ductile rheological conditions are expected. Though numerous studies have contributed to the current understanding of the causative dynamics driving slab seismicity below the brittle-ductile transition in different subduction zones^{8,9,11,15}, they cannot resolve this apparent inconsistency and a gap in knowledge remains with respect to the southern Central Andes.

In this study, we carry out an integrative analysis of the relationship between the observed seismicity distribution, seismic properties, and the 3D geometrical configuration of the oceanic plate to investigate potential mechanisms influencing the seismic behaviour of the slab. We take advantage of a recent full waveform seismic tomography model of the southern Central Andes²³ to demonstrate the existence of a causative relationship between the state of hydration of the mantle and recorded slab seismicity, both for intra-slab and inter-plate events^{21,24,25} (see “Methods” section). We further investigate how in regions of likely slow reaction kinetics and small fluid input to the overriding plate seismic activity can be locally enhanced by flexural stress associated with mapped variations in slab geometry. Overall, although a direct comparison of seismic velocity structure and seismic behaviour is generally well established, the integrative framework presented in our investigation adds thermomechanical and geological constraints to minimise the degree of freedom and non-uniqueness of geodynamical interpretations derived from geophysical modelling.

Results and discussion

To infer the driving physical mechanisms responsible for brittle failure requires knowledge of parameters such as the state of hydration of the mantle and slab geometry. Seismic tomography, due to the sensitivity of P- and S-wave velocities to lithology, fluid/melt-content and temperature, can be used as a proxy to investigate the state of hydration of the mantle^{26–28} (Supplementary Fig. 2). Specifically, low Vp/Vs (1.65–1.8) characterise dry peridotite²⁹, whereas high Vp/Vs (>2) indicate a hydrated mantle with free fluids^{30,31}. Intermediate Vp/Vs values between 1.8 and 1.9 likely correspond to a serpentinized mantle^{29,32–34}. In the oceanic mantle, serpentinization may result from water penetration along normal faults cross-cutting the slab³⁵; conversely, in the mantle wedge, serpentinite is formed from fluids migrating upwards from the subducting slab³⁶. Ascent of fluids from the subducting slab through the mantle of the overriding plate may drive partial melting below the volcanic arc, likewise leading to an increase in Vp/Vs (>1.9)³⁷. Finally, very low Vp/Vs (<1.65) may be indicative of a hydrated and anisotropic mantle, the foliation of antigorite or the presence of a network of preferentially oriented cracks^{30,38,39}.

Here, we analyse the Vp/Vs distribution from the full-waveform inversion tomography model²³. In the following, we discuss our results relying on (i) three cross sections perpendicular to the trench, considered representative of the different subduction segments (Fig. 2a–c); (ii) a N–S cross section along the forearc (Fig. 2d); and (iii) a map along a constant depth of 90 km, which corresponds to the mantle of the overriding plate immediately above the slab in the flat-subduction segment (Fig. 3). Although the tomographic inversion solves for Vs radial anisotropy (i.e., Vsv and Vsh) to avoid introducing artifacts into the isotropic model, it is not robustly constrained⁴⁰ and we thus refrain from interpreting it.

The W–E cross sections depict an across-strike variability in Vp/Vs indicative of progressive eastward dehydration of the oceanic mantle (Fig. 2). The southernmost part of the flat-slab segment (32°S–33°S) shows a very low ratio (<1.65) at depths shallower than 50 km, which can arise in an anisotropic mantle, where anisotropy could be due to the foliation of antigorite or the presence of an oriented network of fluid-filled cracks^{30,38,39} (S1, O1; Fig. 2a). Between 50 and 100 km, the ratio within the slab and the mantle of the overriding plate increases from intermediate (1.65–1.8; S2, O2; Fig. 2a) to high values (1.8–1.9; S3, O3; Fig. 2a), indicating mantle serpentinization. At ~80 km, the Vp/Vs ratio reaches values >1.9 (S4, O4; Fig. 2a), suggesting

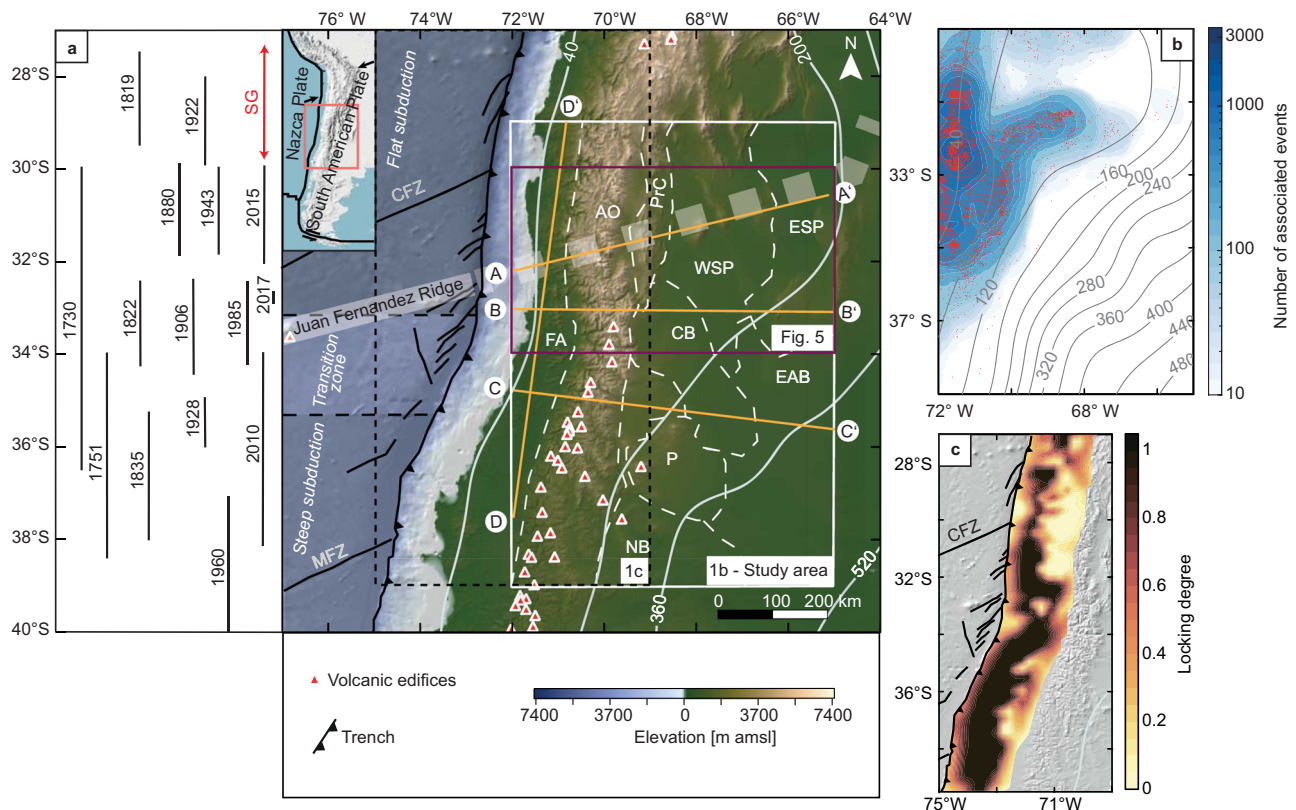

Fig. 1 The southern Central Andes and distribution of slab seismicity. a Main panel: topography and bathymetry of the southern Central Andes based on the ETOPO1 global relief model⁸⁹. The white rectangle encloses the extent of the area considered in this study (area of Fig. 1b); the black dashed rectangle encloses the area shown in Fig. 1c; the purple rectangle encloses the area shown in Fig. 5. Black-dashed lines in the oceanic domain mark the boundaries between subduction segments (flat slab in the north, steep slab in the south). Fracture zones of the Nazca Plate⁷⁵ are highlighted by solid black lines. Abbreviations of main fracture zones: MFZ = Mocha Fracture Zone; CFZ = Challenger Fracture Zone. White lines show the isobath contours (km below mean sea level) of top of the slab (based on the Slab2 model⁷⁵). The wide transparent white line denotes the position of offshore (full line) and projected onshore (dashed line) tracks of the Juan Fernandez Ridge (JFR)⁹⁰. The red triangles depict locations of active volcanoes⁹¹. The orange lines denote locations of profiles shown in Fig. 2. The boundaries between the main morphotectonic provinces are shown by white dashed lines. Abbreviations of main tectonic provinces: AO Andean orogen, CB Cuyo Basin, ESP Eastern Sierras Pampeanas, EAB extra-Andean basins, FA forearc, NB Neuquén Basin, P Payenia volcanic province, Prc Precordillera, WSP Western Sierras Pampeanas. Left panel: extent of historical seismic ruptures⁹². Seismic gaps (SG) are shown with red lines. **b** Seismic-event density (logarithmic scale) derived for a circular bin of 75 km radius for slab seismicity²¹. Seismicity marked by red dots. hydrated conditions with a free fluid phase. Deeper than 100 km, the ratio decreases from values around 1.8 (S5; Fig. 2a) in the central part of the slab to intermediate and low values (1.65–1.8; S6, O5, O6; Fig. 2a) within the top part of the slab and within the overlying mantle. While the V_p/V_s values in the central part of the slab likely indicate a serpentinized mantle, the O6 anomaly seems to indicate either dry or anisotropic hydrated conditions. A dry slab that underwent complete eclogitization and deserpentinization in its topmost domain would imply high densities; this, in turn, is difficult to reconcile with the buoyancy needed to maintain the sub-horizontal subduction angle of the slab in these domains. Our preferred interpretation is that the slab is still hydrated, but the decrease in V_p/V_s may be partly due to wave-propagation artefacts in anisotropic minerals. Indeed, antigorite is stable at upper-mantle pressures and temperatures $<650^\circ\text{C}$ ³⁶, which is consistent with the conditions modelled in this region of the flat slab segment ($\sim 600^\circ\text{C}$)^{41,42}. However, Anderson et al.⁴³ reported moderate anisotropy ($\sim 4\%$) for this part of the slab, which is inconsistent with the very strong seismic anisotropic signature ($>30\%$)³² of foliated antigorite. Instead, these authors attributed the medium-scale seismic anisotropy to sheared olivine. In this context, the combined observation of low to intermediate V_p/V_s ratios and moderate anisotropy in the flat slab

could indicate hydrated peridotite with isotropic antigorite and anisotropic olivine⁴⁴.

For the mantle of the continental plate above the flat slab, there is little information on seismic anisotropy to draw more extensive conclusions on its hydration state. We can speculate that dehydration reactions within the slab being kinetically delayed due to low temperatures would imply less fluid release detectable by seismic methods in the overlying lithospheric mantle, which could explain the observed low V_p/V_s in our study. An additional factor contributing to the smaller fluid content within the mantle of the overriding plate could be the pressure gradient generated by the slab re-steepening, which would cause the fluids released by the dehydration reactions in the central part of the slab to be diverted from their expected vertical pathways further to the east⁴⁵. The increase in V_p/V_s (~ 1.7) from low values at 68.5°W to high (~ 1.8) values at 67.5°W (Fig. 2a) lends support to this hypothesis.

Unlike the flat-slab segment, the transitional segment to the steeper subduction angle displays a more uniform V_p/V_s distribution. Below 50 km, an increase from low and intermediate (1.65–1.9; S7, S8, O7, O8) to high (>1.9 ; S9, O9) values marks the transition from serpentinized³² rocks to a mantle with a free fluid phase³⁰ (Fig. 2b). At depths >100 – 150 km, V_p/V_s decreases to values

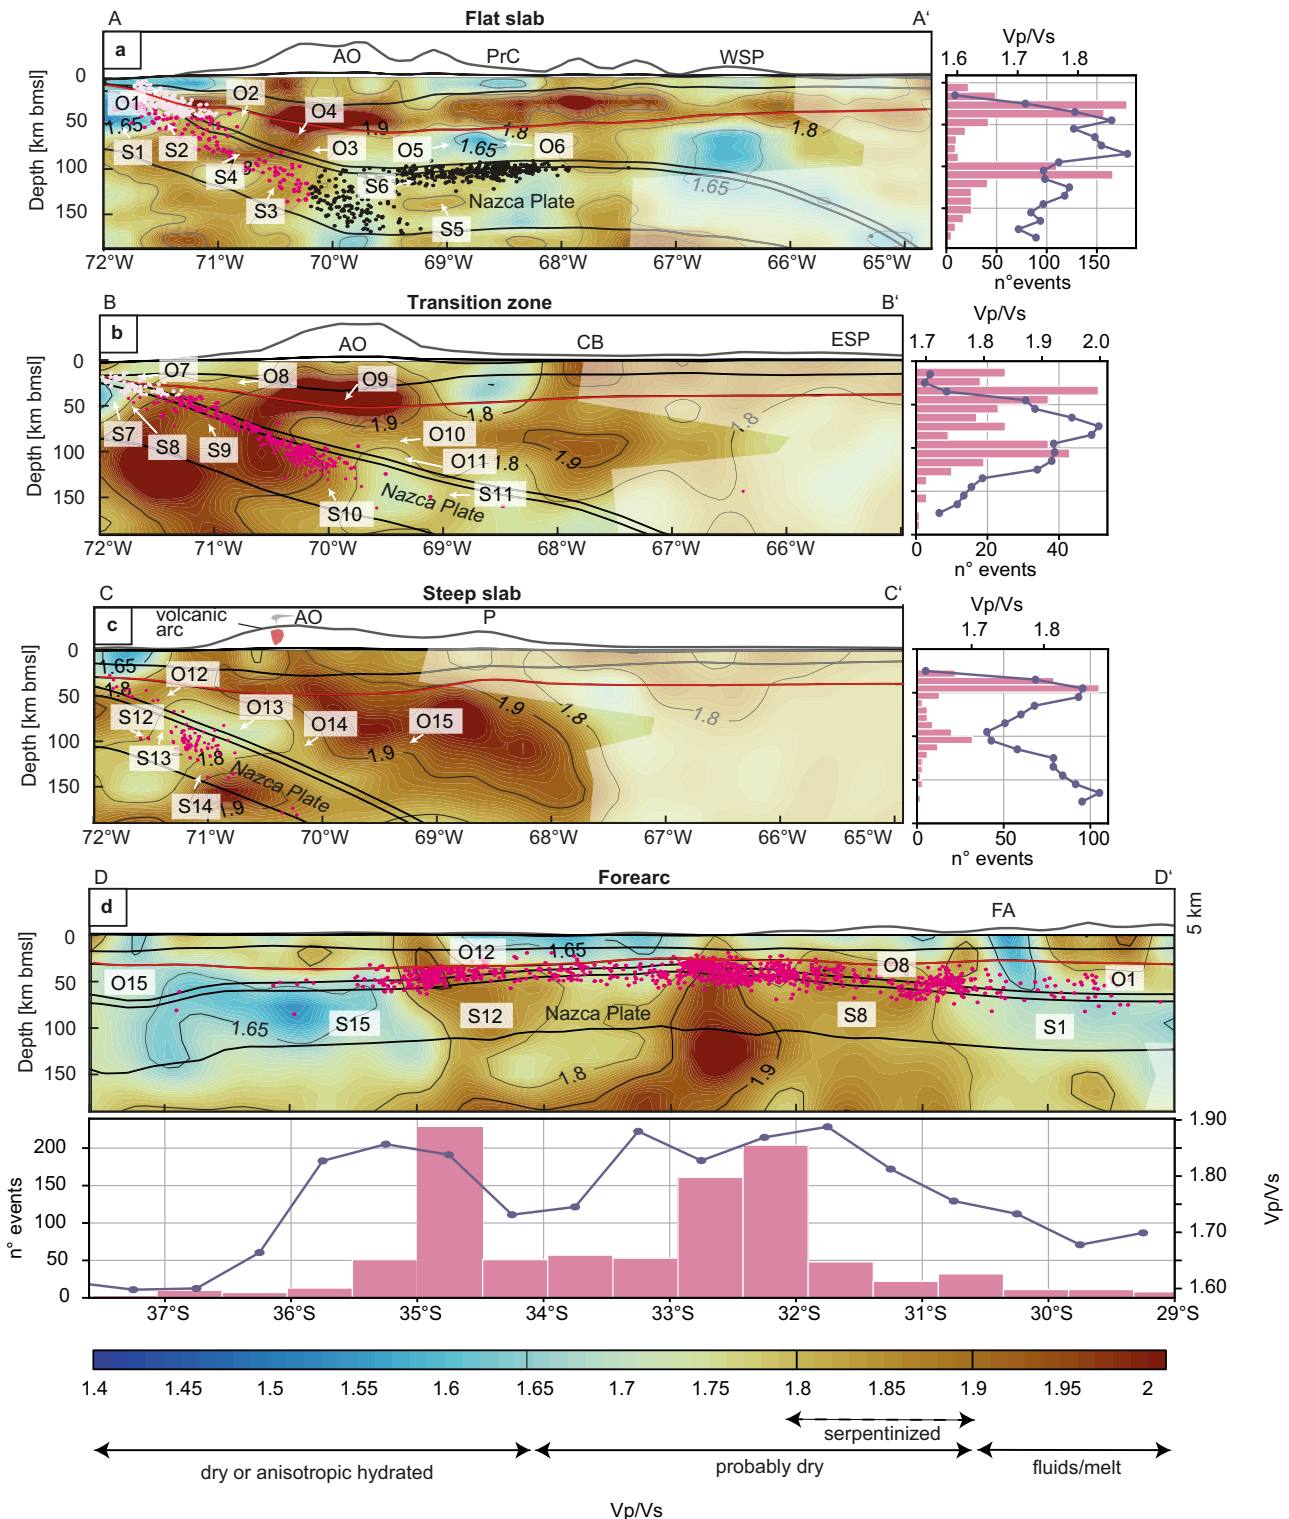

Fig. 2 Vp/Vs ratio of the southern Central Andes. **a-d** Vp/Vs ratio along cross-sections A-D (see Figs. 1 or 3 for profile locations). Areas with poor resolution are masked with semi-transparent white shading. Dots show the location of hypocentres of slab seismicity²¹ within 5 km distance from each profile. Pale pink dots denote seismicity due to brittle stick-slip assisted by dehydration, magenta dots mark dehydration-related seismicity, while black dots show events attributed to flexure-assisted seismicity. The interfaces of the lithospheric model units are marked by black lines, except for the Moho discontinuity, which is shown by red lines. On top of each profile, topography of the upper plate is displayed with a vertical exaggeration of 10:1. Right panels in **a-c** and bottom panel in **d** show the histogram of slab seismicity and the average Vp/Vs within the slab as a function of depth and latitude, respectively.

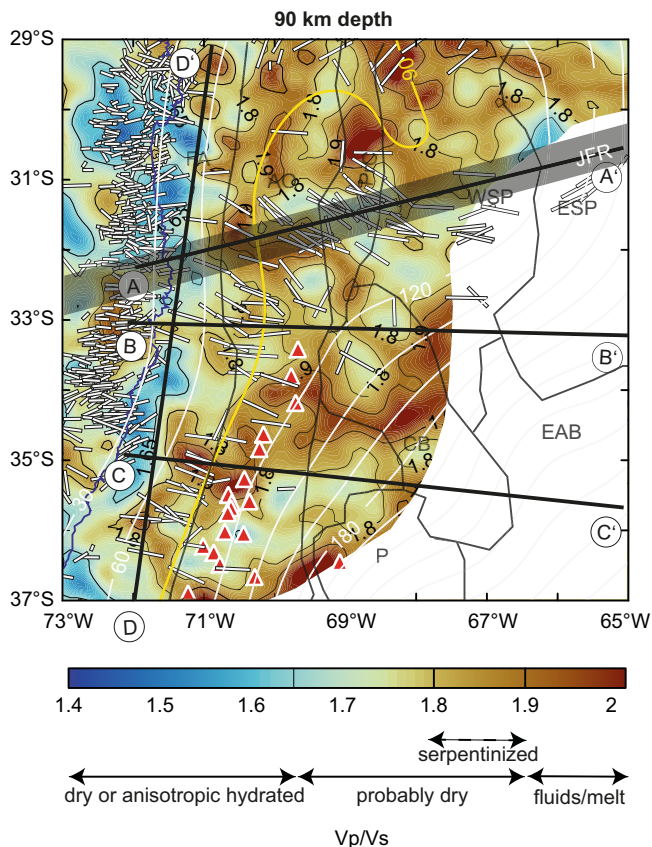

Fig. 3 Vp/Vs variations at 90 km depth. Additionally shown are profile locations of Fig. 2 (black lines), depth contours to the top of the slab at 30-km intervals (white thin lines, except 90 km-depth contour in yellow), the dominant orientation of the T-axes of focal mechanisms^{24,25} projected horizontally (white thick bars), the projected onshore (thick grey line) tracks of the Juan Fernandez Ridge (JFR)⁹⁰, the active magmatic arc (red triangles), and the coastline (blue line). For abbreviations of morphotectonic provinces, see Fig. 1.

<1.8 (S10, S11, O10, O11; Fig. 2b), which indicates a slab that has already been dehydrated²⁹.

The steep-slab segment depicts a region of intermediate Vp/Vs values (1.8–1.9; S12, O12; Fig. 2c) within the slab domain proper and the overriding plate mantle extending down to 60 km, which again indicates a serpentinized³² mantle. Between 75 and 120 km, we notice a local Vp/Vs low (1.7–1.8) within the slab (S13) and the mantle of the overriding plate (O13), suggesting dry conditions²⁹ (Fig. 2c). However, to interpret a fully dehydrated mantle at these depths is difficult, especially given the observed Vp/Vs increase (>1.8) below 120 km (S14, O14, O15; Fig. 2c) and the presence of the active volcanic arc immediately above in the upper plate. Our preferred alternative scenario to reconcile the observed intermediate Vp/Vs with the overlying volcanic activity is the presence of hydrated but anisotropic mantle.

The southern Central Andes also display large along-strike variability in Vp/Vs (Fig. 2d–e). For instance, at 90 km depth, the orogenic domain displays intermediate (1.8–1.9) to high (>1.9) values only in its central part (between 31°S–35°S, S8, S12, O8, O12; Fig. 2d), while in the northern and southern regions Vp/Vs decreases to values between 1.65–1.8 (S1, S15, O1, O15; Fig. 2d). We can explain this enhanced hydration in the central orogenic domain with its proximity to the Juan Fernandez Ridge, a seamount chain subducting at 33°S (Fig. 1a). This ridge is associated with pervasive faulting⁴⁶, which enables fluids to reach the and

hydrate the oceanic mantle. These fluids are released through dehydration reactions after subduction and ultimately enhance hydration of the overriding mantle⁴⁷. South of 33°S, the active magmatic arc is located near the western edge of an extended region of high (>1.8–1.9) Vp/Vs values in the mantle wedge at 90 km depth (Fig. 3). This suggests that the observed increase in Vp/Vs can indeed be associated with the presence of melts due to the reopening of the mantle wedge and the re-steepening of the Nazca Plate^{42,48,49}. Finally, Vp/Vs is high (1.84–1.9) beneath the Precordillera and the western Sierras Pampeanas (29°S–31°S, Fig. 2e), which spatially correlates with a zone of low Vs (Supplementary Fig. 3) interpreted by Gao et al.²³ as a region of slab thinning and tearing along the inland projection of the Juan Fernandez Ridge.

Intra-slab seismicity, fluids and flexure. We now compare the Vp/Vs distribution with the distribution of inter-plate and intra-slab seismicity. First, for the subduction segment in the transition zone (33°S–35°S), slab seismicity at depths shallower than 120 km is limited to the slab domain with high Vp/Vs (>1.8, S8–S10, Fig. 2b). Secondly, seismicity also occurs below a region of hydrated continental mantle with a high velocity ratio (O8–O10, Fig. 2b, d; O12, Fig. 2d). This points to a spatial correlation between slab seismicity and mantle hydration in this region. Seismicity ceases quite abruptly where the slab undergoes (nearly) complete dehydration (as indicated by a lower Vp/Vs) and is not able to release any more fluids to the mantle of the overriding continental plate (e.g. S11, O11; Fig. 2b; S15, O15, Fig. 2d). Likewise, the observed change from medium (1.7–1.8) to high (>1.9) Vp/Vs in the overriding mantle spatially correlates with the location of the active volcanic arc (Figs. 2d and 3) in the transition zone and steep-slab segments, at 69°W–70°W, which confirms the presence of fluid-related melts. In short, fluids responsible for the generation of partial melts, which feed the volcanic arc south of 33°S, are released west of 70°W and the downdip limit of intra-slab seismicity is actively controlled by the availability of fluids in the slab mantle.

The spatial relationship between the regions of mantle hydration and the occurrence of slab seismicity showcases how fluids play a primary role in the promotion of intermediate depth seismicity. The release of fluids increases pore pressure and enhances frictional weakening of the slab, thereby triggering intra-slab seismicity even in regions where brittle failure should be inhibited given local conditions of lithostatic pressure and temperature. In this context, metamorphic reactions of constitutive minerals in the oceanic crust (e.g. amphibole and epidote breakdown during eclogitization^{9,50}) and in the mantle (e.g. serpentine breakdown^{10,28}) can lower the rock frictional strength, thereby offering an explanation for the observed intra-slab seismicity at intermediate depths (50–300 km). Fluids from these reactions can migrate trenchward, enabling intraplate earthquakes at shallower depths (~40 km) through a variety of mechanisms^{51,52}: (i) pore-pressure increase (dehydration embrittlement^{8–10,53,54}; (ii) grain-size reduction¹³; and (iii) dehydration-related stress transfer from the hydrous phases to the dry host rock¹¹. Since these reactions all affect the state of hydration of the slab and overlying lithospheric mantle, it should be expected that hydrated regions are seismically more active than dry regions^{55–58}, as observed in our analysis. Similar relationships between seismic velocities and the distribution of seismicity have been found in other subduction zones, such as Cascadia^{55,56}, Hirukangi⁵⁷ and the north-western Pacific margin⁵⁸.

In the flat-slab segment (29°S–33°S), the relationship between slab seismicity and hydration of the mantle is not straightforward.

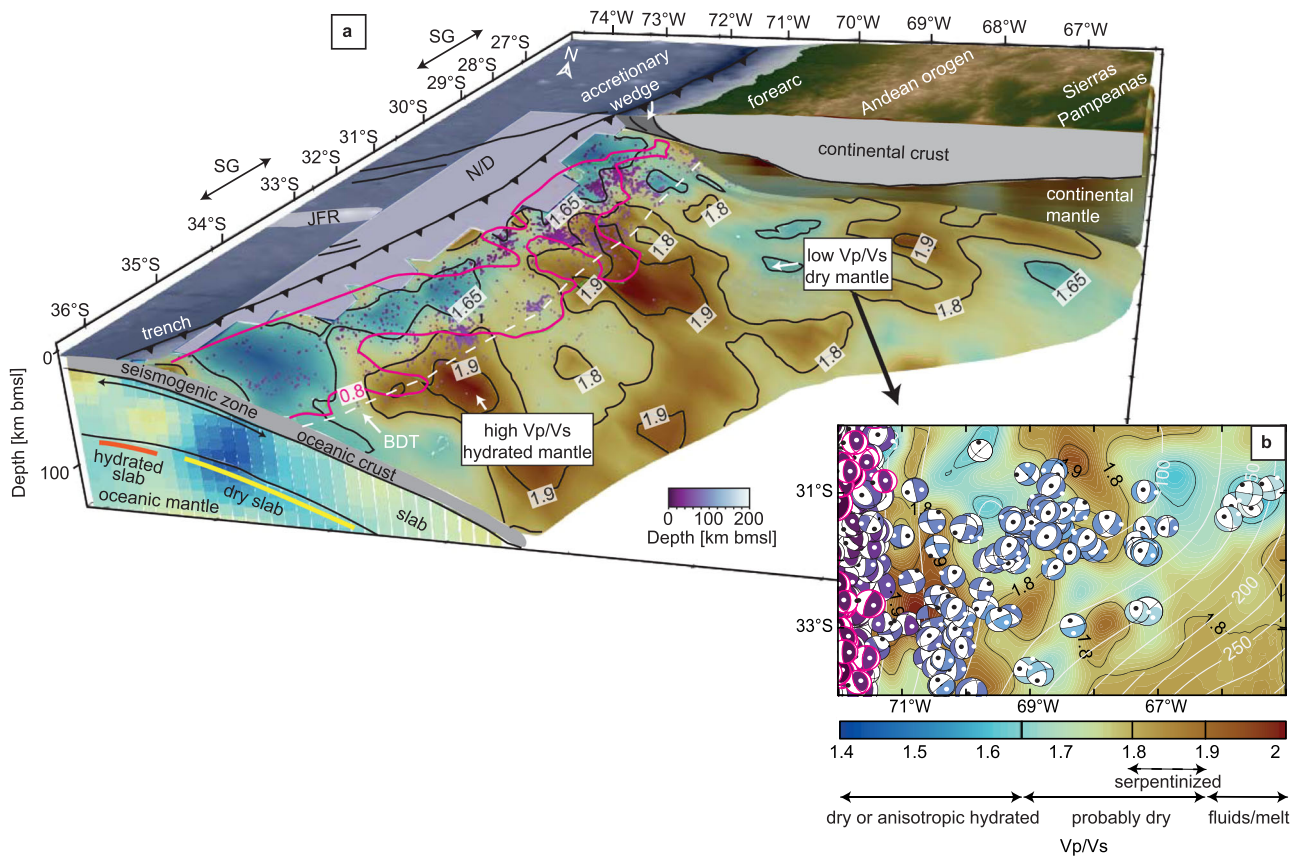

Fig. 4 Conceptual model of the Vp/Vs ratios and relationship with slab seismicity. **a** 3D diagram of Vp/Vs distribution reflecting the state of hydration within the mantle and the subduction interface, and slab seismicity colour-coded by hypocentral depth. The extent of labelled dry or hydrated slab only pertains to the cross-sections in Fig. 2a, b and strongly varies along the strike of the subduction zone. The dashed white line shows the brittle ductile transition (BDT)²². Magenta-coloured contours show the areas with a high degree of locking⁶⁷. The 3D lithospheric layers used for this graph are based on the structural model of Rodríguez Picada et al.⁹³. **b** Vp/Vs distribution in the region of the flat-slab to steep-dip subduction transition overlain with focal mechanism solutions of inter-plate and intra-slab earthquakes^{24,25}, colour-coded by depth and with white and black dots indicating P and T axes, respectively. The inter-plate events are marked with a magenta circular outline. The isobath contours of the top of the slab⁷⁵ are shown in white lines.

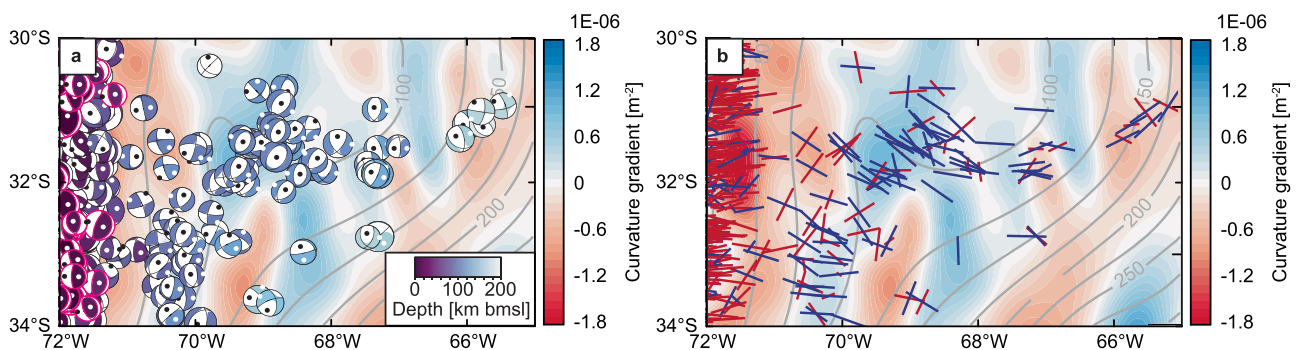

Fig. 5 Slab geometry and slab seismicity in the region of the flat-slab to steep-dip subduction transition. Curvature gradient of the top of the slab in the transition between flat and steep-slab subduction (Supplementary Note 2), superposed with **a** focal mechanism solutions of inter-plate and intra-slab earthquakes^{24,25} colour-coded by depth (dots show the orientation of the P- (black) and T- (white) axes); and **b** P- (red) and T- (blue) axes projected horizontally. Only the sub-horizontal axes (plunge <45°) are shown. The inter-plate events in **a** are bordered in magenta. The isobath contours of the top of the slab are shown in grey lines. The geometry of the top of the slab was taken from Rodríguez Picada et al.⁹³, based on Hayes et al.⁷⁵.

For the flat-slab region between 31°S and 32°S, seismicity shallower than 80 km occurs where the slab is hydrated (S1–S3, Fig. 2a). However, this is not the case for the seismicity at larger depths (80–100 km), east of the mantle wedge corner, beneath the Precordillera and the Sierras Pampeanas (S6, Fig. 2a). Here, the upper cluster of seismicity close to the top surface of the slab is localised below a domain in the continental mantle and the

subduction interface that is characterised by low Vp/Vs (<1.8, O5, O6) and, therefore, by low fluid content (Figs 2a, 4 and 5). Unlike the southern part of the flat-slab segment, the overriding plate mantle, and the subduction interface in the northern part (29°S–31°S) are characterised by high Vp/Vs (1.8); these areas are thus likely hydrated, while the underlying subducting plate is aseismic (Figs 3–5). These two observations (i.e., seismic and

partially anhydrous overriding plate mantle in the southern flat segment versus aseismic and hydrated overriding plate mantle in the northern flat segment) make it difficult to link the observed intra-slab seismicity in the flat-slab segment to dehydration reactions^{59,60}. When examining the earthquake focal-mechanism solutions in the region^{24,25} (Fig. 5a), we observe a lack of compressional mechanisms, which also rules out the effect of plate convergence as the main trigger for these earthquakes. Seismicity in these domains could instead be related to enhanced bending and unbending stresses in the presence of a non-fluid related weakening mechanism where the slab resumes its steep subduction angle east of 65°W, beneath the Sierras Pampeanas and, to the south, beneath the Cuyo Basin. A possible mechanism is thermal shear instability, where a positive feedback between strain and temperature reduces friction and favours brittle rupture^{13,14}. This hypothesis agrees with the findings of previous studies^{15,16} suggesting that, in regions of intermediate to low pore-fluid pressure, flexural stresses can be more relevant than fluids in triggering seismicity. Variations in the geometry of the subducting slab may have triggered seismicity within its bending and unbending parts, if the effective strain rates associated with slab flexure exceed those associated with slab pull^{15,16,61,62}. Additional evidence for such a control by slab flexure on the occurrence of seismicity comes from the observed spatial correlation between the flexural regime and the orientation of the earthquake moment tensors^{15,16}. For example, slab segments with positive curvature (i.e. concave down) gradients are usually characterised by earthquake moment tensors with down-dip tensional axes in the upper part of the slab, whereas those with negative curvature gradients display seismicity associated with down-dip compressional axes (Supplementary Fig. 4)^{4,16}. Indeed, we found a rather striking spatial correlation between seismicity and slab geometry in the southern Central Andes based on the orientation of the P- and T-axes of focal mechanisms^{24,25} (Fig. 5b). The focal mechanism solutions with a down-dip orientation of the P-axis spatially correlate spatially with the portions of the slab characterised by a negative curvature gradient due to unbending in the transition from flat to steeper subduction angles (Fig. 5b), and equivalently for down-dip T-axes indicating bending. This supports the notion that inter-plate seismicity in these regions is triggered by internal deformation of the slab, as required by the flat-slab geometry.

In the steep-slab segment (35°S–39°S), seismicity is generally limited to domains of hydrated mantle with high Vp/Vs (S12, S14; Fig. 2c). However, similarly to events below the Precordillera and Sierras Pampeanas, the largest seismic cluster in the steep-slab segment correlates at 35°S with a local low in Vp/Vs at 80–120 km (S13, Fig. 2c). Unlike the flat-slab cluster, the steep-slab segment lacks unbending portions below 20 km, making it difficult to relate these events to flexural stresses. An alternative explanation to reconcile the low Vp/Vs ratio with the seismic activity is to consider that the mantle here is hydrated but anisotropic. To date there is no direct evidence of anisotropy in this part of the slab, hence further work targeting the anisotropic signature of the steep-slab segment is needed to fully explain this feature.

Interplate seismicity, fluids and locking degree. A wide range of inter-plate seismic phenomena have been attributed to the effects of high pore-fluid pressure, including deepening of the updip limit of background seismicity and trenchward propagation of megathrust earthquakes⁶³. Typically, an increase in pore pressure is linked to release of fluids, which can lead to enhanced frictional weakening of the subduction interface. In this case, fluid sources encompass: (i) pore water in the sediments released by

compaction and (ii) bound water within hydrous minerals of the sediments, oceanic crust, and mantle released by dehydration reactions⁶³. Dewatering due to sediment compaction is restricted to the shallow part of the fault interface (3–7 km depth)⁶⁴, while fluids from dehydration reactions become predominant below this depth. For the Chilean margin between 37°S and 42°S, previous studies have identified a correlation between the state of hydration of the mantle and pore-fluid content, the spatial extent of locked zones along the subduction interface⁶⁵, and the recurrence time of great earthquakes⁶⁶. They found that domains of high Vp/Vs, interpreted as being dominated by high pore-fluid pressure, correlate with areas of a low degree of locking⁶⁵, which are able to slip predominantly aseismically. In contrast, interfaces with low Vp/Vs and thus inferred low pore-fluid pressure, display a high degree of locking⁶⁵ and tend to cause seismic slip less frequently. Our findings support these observations and expand their spatial coverage. For the domains of the southern Central Andes between 29°S and 39°S we have been able to detect a similar correlation between low Vp/Vs and locked areas⁶⁷ along the plate interface (Fig. 4a and Supplementary Fig. 5). This suggests that variations in pore-fluid pressure should be considered as the main factor controlling pre-seismic locking along the plate interface in the southern Central Andes. In agreement with previous studies⁶⁵, we can correlate the presence of N–S variations in pore-fluid pressures with the distribution of fracture zones in the Nazca plate (Fig. 1a). Due to this structural control, slab regions that underwent a higher degree of fracturing are prone to contain more fluids and are characterised by a higher degree of hydrologic connectivity. This in turn translates into higher Vp/Vs values and a lower degree of plate locking compared to regions where fracturing is less intense.

Our findings therefore provide new insights into the general characteristics of regional seismic hazard of the southern Central Andes. At the latitudes of the flat-slab segment, large megathrust earthquakes exhibit a recurrence interval of ~60–90 year⁶⁸, based on the frequency of the most recent historical events with $M \geq 8$ (AD 1822, 1906, and 1985 in the Valparaíso sub-segment and 1880, 1943 and 2015 in the Illapel sub-segment). The segment north of 29°S, which last experienced a major rupture in 1922 represents a seismic gap, the so-called Atacama gap (Fig. 1a). Geodetic measurements furthermore indicate that the near-trench subduction interface at these latitudes is locked⁶⁹ (Figs. 1c and 4a). This raises the question as to how a seismogenic rupture will be produced along these portions of the subduction interface and if stresses will be released either in the form of either several large but not great earthquakes ($M7-8$) or during one great earthquake ($M > 8.5$). Regions that are subjected to high fluid pressures are generally weaker and more unstable under the stress build-up than faults under dry conditions^{63,70}. As such, weak faults are more prone to seismic rupture and favour stress release by several earthquakes of moderate magnitude⁶⁶. Conversely, regions with a drier interface can accumulate elastic energy for longer periods of time, which can then be released by less frequent, but very high-magnitude earthquakes. The locked region, the subduction interface displays low Vp/Vs, thereby indicating dry conditions (Fig. 4a, b). It thus follows that this domain is likely to be able to generate a great earthquake in the future, a conclusion that calls for increased geodetic monitoring of the seafloor to better assess the updip limit of locking and thus provide more accurate estimates of the size of a future earthquake.

Conclusions

This contribution examines the relationship between observed seismicity, seismic attributes, and the 3D configuration of the

oceanic plate to determine the mechanisms impacting the seismic behaviour of the slab in the southern Central Andes. Our synopsis of Vp/Vs data in the area from a regional full waveform inversion tomography suggests that local fluid overpressure resulting from disequilibrium compaction beneath the forearc and dehydration reactions of hydrous minerals below the remaining regions are responsible for embrittlement of the lithosphere and the triggering of intra-slab and inter-plate seismicity in the transition zone between flat and steep subduction and within steep-slab segments of the southern Central Andes. The distribution of Vp/Vs in the flat-slab segment suggests that: (i) dehydration reactions are being kinematically delayed due to low-temperature conditions and (ii) the migration pathways of fluids are influenced by pressure gradients generated by unbending stresses from variations in the slab geometry. Here, seismicity occurs in regions where Vp/Vs is low and fluids are thus unlikely to cause sufficient weakening to induce rupture. Instead, bending and unbending stresses in the presence of thermal shear instabilities constitute the most likely mechanism to explain the local cluster of seismicity observed in these regions.

Methods

Seismic catalogue. We derived the seismicity distribution for the study area between 1964 and 2018 from the reviewed bulletin of the International Seismological Centre^{71–74}, from which we removed all events with fixed depth or a depth error >5 km. We then filtered the events related to the oceanic slab ('slab seismicity'), according to their proximity to the subduction interface, which is represented by the top of the slab from the Slab2 subduction zone geometry model⁷⁵. All events below the top of the slab, with a tolerance given by the uncertainty of the Slab2 model were extracted, a total of 9125 slab earthquakes, which comprises both plate interface events and intraslab events. To classify the events into 'intra-slab' and 'inter-plate' seismicity, we relied on the focal mechanism solutions from the GCMT catalogue^{24,25}. An earthquake was considered as inter-plate seismicity if it fulfilled four criteria⁷⁶: (i) it occurs in the interval defined by the depth of the top slab \pm the uncertainty of the Slab2 model⁷⁵; (ii) the slip vector orientation represents thrusting; (iii) the strike of one of the nodal planes is equal to the strike of the top slab surface from Slab2⁷⁵ ($\pm 15^\circ$); and (iv) the dip angle of one of the nodal planes differs $<15^\circ$ from the dip angle of the top of the slab surface⁷⁵. The remaining earthquakes were considered as intra-slab seismicity. There were 873 events with GCMT mechanisms of which 114 events were classified as intra-slab events and 759 as inter-plate events.

P- and S- wave seismic tomography. We derived the Vp/Vs model from the isotropic P and S velocity models presented in Gao et al.²³. Here, we only provide a brief summary of the methodology followed to construct the tomography model; more technical details about the inversion workflow can be found in the original publication²³.

The seismic velocity model is the result of a multi-scale full waveform inversion⁶ based on the adjoint methodology^{77,78}, starting from the 3D seismic velocity model SP12RTS⁷⁷. Solutions of the visco-elastic wave equation in a radially anisotropic Earth model are obtained from Salvus^{77,79}.

Long-wavelength surface topography from the EGM2008 Geoid⁸⁰ and Earth2014 global topography model⁸¹ with Earth ellipticity according to WGS84 and the Moho depth from the global model CRUST1.0⁸² were implemented by deforming the mesh grid vertically. The surface topography and Moho depth have been filtered with a maximum angular order of 128, equivalent to a spatial resolution of 155 km. In order to constrain the deep structure of the upper mantle, we initialised our inversion from long-period surface wave data at 60–120 s and progressed in seven stages to a final period range of 12–120 s. The progressive extension to shorter periods mitigates the risk of falling into local minima. The model updates are driven by the Limited-Memory Broyden–Fletcher–Goldfarb–Shanno algorithm (L-BFGS)⁸³. We employ the Time-Frequency Phase Shift and Cross-Correlation-Coefficient misfits as misfit functions during stages 1–5 and 6–7, respectively, with the assistance of the Large-scale Seismic Inversion Framework 2.0^{84,85}.

Data availability

Waveform data and station meta data for the seismic tomography were downloaded using the ObsPy¹⁶ module through the International Federation of Digital Seismograph Net291 works (FDSN) web services from GEOFON Data Management Center (<https://geofon.gfz-potsdam.de/waveform/archive/>) and Incorporated Research Institutions for Seismology Data Management Center (IRIS-DMC, <http://www.iris.edu/ds/nodes/dmc/>). The seismic tomography model can be accessed via GFZ data services (<https://doi.org/10.5880/GFZ.2.4.2021.008>).

The earthquake hypocentres were taken from the ISC reviewed bulletin²¹. The provider agencies are: International Seismological Centre⁷¹ (UK), Centro Sismológico Nacional (Chile), Instituto Nacional de Prevención Sísmica⁷³ (Argentina), International Data Centre (Austria, <https://www.ctbto.org/>) and National Earthquake Information Centre⁷² (USA, <https://www.usgs.gov/programs/earthquake-hazards/national-earthquake-information-center-neic>). The focal mechanisms solutions in Figs. 3–5 were taken from the Global Centroid Moment Tensor catalog (<https://www.globalcmt.org>). The 3D structural model used to plot the geometry of the lithospheric layers in Fig. 4a and to calculate the curvature of the slab can be accessed via the GFZ data services (<https://doi.org/10.5880/GFZ.4.5.2020.001>). The colour scales used in Figs. 1–4 were taken from Scientific Colour Maps (<https://doi.org/10.5281/zenodo.4491293>).

Code availability

Code sharing not applicable to this article as no code was generated during the current study. Plots were generated with Adobe Illustrator, QGIS⁸⁶, Generic Mapping Tools⁸⁷ and Paraview⁸⁸.

Acknowledgements

This research was funded by the Deutsche Forschungsgemeinschaft (DFG) and the Federal State of Brandenburg under the auspices of the International Research Training Group IGK2018 “SuRFace processes, TEctonics and GEoresources: The Andean foreland basin of Argentina” (STRATEGY DFG grant STR 373/34-1). Y.G. was supported by Freie Universität Berlin - China Scholarship Council Program. The seismic tomography processing was supported by the Swiss National Supercomputing Center (CSCS) in the form of computing time grants s868 and s1040. We thank Marianne Métois for providing the grid of locking degree and three anonymous reviewers for their constructive comments.

Author contributions

C.R.P. conceived and designed the main conceptual ideas of this work, processed the seismic catalogue, provided the 3D lithospheric model, performed the analysis and wrote the main parts of the manuscript. Y.G. conducted the seismic tomography imaging, and

contributed to the analysis of the results and the writing of the manuscript. M.C. helped devising the main conceptual ideas and proof outline of this work, and contributed to the analysis of the results and the writing of the manuscript. J.B. and F.T. contributed to the analysis of the results and the writing of the manuscript. M.S.W. and M.S. supervised the study and contributed to the interpretation of results and the writing of the paper.
