Health communication has relevance for virtually every aspect of health and well-being, including disease prevention. This review explored the effectiveness of communications in enhancing the adoption of or adherence to behavioural interventions (non-pharmaceutical interventions (NPIs)) related to COVID-19. The review takes the UK as a case study and focuses on self-reported behaviours (e.g. social distancing). It also reviews the psychosocial determinants of adherence. Searches were conducted using PubMed, Scopus, CINAL, ASSIA and iCite databases. Eleven thousand five hundred records were identified and 13 were included in the final sample. Included studies suggest that NPI adoption or adherence was generally high, and communication had significant impacts, with key themes including clarity and consistency, trust and control. Based on the evidence in this review, features of effective

communication in the context of NPI adoption or adherence are (i) information should be conveyed clearly and conflicting (mixed) messages should be avoided; (ii) information should be conveyed by trusted sources (e.g. health authorities) and (iii) communication should strike a balance between being authoritative but avoiding language seen as controlling (e.g. 'you must'). Future research should prioritize quantitative, experimental and longitudinal study designs, that focus specifically on communication as an intervention, and which measure behaviour.

This article is part of the theme issue 'The effectiveness of non-pharmaceutical interventions on the COVID-19 pandemic: the evidence'.

1. Introduction

Health communication has relevance for virtually every aspect of health and well-being, including disease prevention [1]. In the context of public health emergencies like the COVID-19 pandemic, effective risk communication can enable people to take informed decisions to protect themselves and others, reduce illness and save lives [2]. During the COVID-19 pandemic, rapid, effective communication was needed to convey accurate information around non-pharmaceutical interventions (NPIs), like facemask wearing, self-isolation and physical distancing from governments, health authorities, scientists and other key health actors to the public. There is a growing body of evidence looking at adherence to COVID-19 public health behavioural interventions (hereafter NPIs). This evidence from the UK suggests that overall adherence to NPIs was generally high, particularly in the early stages of the pandemic, even for the more challenging, 'higher cost' NPIs, like lockdowns [3,4]. There are a number of factors that predict adherence [3,5], but communication is a critical one [6]. It has been suggested that all intervention efforts to change behaviours are communicative acts [1,7]. In a sense, as far as NPIs are concerned, communication can be seen as a 'meta-intervention'. Meta-interventions are procedures that can be designed to change an audience's behaviour with respect to the preventive interventions themselves, including their participation in them [8]. Even if evidence demonstrates that a given NPI, like facemasks, are efficacious in reducing virus transmission in clinical or experimental settings, they are unlikely to be effective in real-world settings if they are not communicated well. Put simply, NPIs are unlikely to be effective, if people are not aware of, or do not understand, whether, when, where or how to do them [7].

Effective communication is therefore cited as a key component of NPIs for COVID-19 [9,10]. 'Health communication' is however difficult to define, precisely because it entails such a broad and inclusive set of constructs or principles [11]. Health communication, as the *exchange of information*, can be seen to entail a number of interrelated components, including (i) a *message* (what information is being communicated and how is it being framed), (ii) a communication channel (which media is the message being sent across), (iii) a communication source (who is sending the message) and (iv) an audience (who is receiving or interpreting the message) [12]. One useful definition is 'the use of communication strategies to inform and influence individual and community decisions that enhance health' [13]. This definition identifies two of the key purposes of health communication: informing (or educating) and influencing (or persuading)—two key functions of behaviour change interventions [14,15].

Communication interventions also do not fall into a 'social vacuum', with a range of social and cultural factors and channels heavily influencing how communicated information is received and processed [1,11,16]. Indeed, disentangling communication from the changing context and nature of the policies and laws being communicated (especially in a rapidly changing public health emergency) is challenging. Furthermore, one increasingly important role of communication has been to combat the COVID-19 'infodemic', characterized as an overabundance of information or misinformation (inaccurate or misleading information, including but not limited to COVID-19 conspiracy theories) shared online via social and other media [17]. This underscores the need

for public health communication to strive to be accessible, actionable by decision-makers, credible and trusted, relevant, timely and understandable [2]. In the context of public health emergencies like COVID-19, it has been suggested that an effective communication strategy is 'a two-way process that involves clear messages, delivered via appropriate platforms, tailored for diverse audiences, and shared by trusted people' [7,16]. Research has further identified that the implementation of interventions operates within a system of key intersecting behavioural components, including capability, opportunity and motivation, which shape their effectiveness [14]. These behavioural conditions have been highlighted as especially important for COVID-19 interventions when considered in the context of implementing change during pandemic restrictions [18].

Some general criticisms of research on behaviour change interventions have been identified. First, although media health campaigns have been seen to have small measurable short-term effects on behaviour change [19], evidence on sustaining behaviour change (maintenance) is relatively limited [20]. Second, the intention-behaviour gap, where people do not necessarily 'follow through' on their intentions by acting, is a well-established known challenge for public health communication [21]. For instance, a recent review on health authorities' health risk communication to the public during pandemics found that evidence on protective behaviour was lacking (with most studies focused on content or engagement with communication media) [22]. This reflects a wider historic concern by critics highlighting the difficulties often found in pointing to health risk communication 'success stories', or interventions that have effectively translated evidence-based principles into action [23].

Building on these broader understandings, for the purposes of this review, we define communication as the conveyance of information around NPIs employed by the UK during the COVID-19 pandemic, including but not limited to social media, print media and television. Also, to maintain high policy relevance and for pragmatic reasons it was decided that the review should be tightly focused on the United Kingdom rather than a broader study of the international evidence from different, confounding social and cultural settings. This evidence review therefore screened and synthesized literature looking at the impact of communication specifically on *behaviours and actions* related to NPIs in the United Kingdom.

(a) Research question

What is the best-available evidence about the effectiveness of communication in improving adoption of, or adherence to, NPIs in relation to COVID-19 in non-healthcare, community-based settings?

The sub-questions of this review are as follows:

1. What is the best-available evidence about the types of communication strategies being used to encourage adoption of, or adherence to, NPIs in relation to COVID-19 in non-healthcare, community-based settings?
2. What is the best-available evidence about which types of communication strategies are the most effective at encouraging adoption of, or adherence to NPIs in relation to COVID-19 in non-healthcare, community-based settings?
3. In the context of communication, what is the best-available evidence about the psychosocial determinants of the adoption of, or adherence to NPIs in relation to COVID-19 in non-healthcare, community-based settings?

2. Methods

Candidate studies were retrieved from the following databases, with search strings developed by the research team in consultation with a Medical Librarian (Swansea University) and following review by substantive experts in the field of COVID-19 and public health communication: (i) PubMed, (ii) Scopus, (iii) CINAL, (iv) ASSIA and (v) iCite's COVID database for preprints.

Box 1. Search strategy.

AND

('communicat*' OR 'health knowledge' OR 'health education' OR 'campaign*' OR 'access to information' OR 'mass communication' OR 'mass medi*' OR 'messag*' OR 'information shar*' OR 'information trans*' OR 'guidance' OR 'public engag*' OR 'public understand*' OR 'misinform*' OR 'disinform*' OR 'infodemic' OR 'conspirac*' OR 'alert' OR 'press conferenc*' OR 'social media' OR 'broadcast*' OR 'health literacy' OR 'nudg*' OR 'prompt*' OR 'persua*' OR 'attitud*' OR 'intention*')

AND

(United Kingdom' OR 'UK' OR 'England' OR 'English' OR 'Wales' OR 'Welsh' OR 'Scotland' OR 'Scottish' OR 'Northern Ireland' OR 'Northern Irish' OR 'British' OR 'Britain')

The search was limited to studies focused on, or including the UK, and was not restricted according to certain study types or designs. The date range for candidate studies was set at 1 January 2020, to coincide with the emergence of COVID-19 as a global pandemic, to 31 December 2022. We used database-specific adaptations of the following generic search string (see electronic supplementary material for details on database-specific search strings) box 1:

Following the removal of duplicates, returned citations were screened independently by two reviewers (S.N.W. and K.D.) at the title/abstract levels. Full papers were screened by four reviewers (S.N.W., J.J., J.K.W. and K.D.) with two reviewers independently reviewing each paper. Disagreements were first additionally reviewed by a third reviewer, before being discussed by the research team and resolved by consensus. Separate inclusion/exclusion criteria were applied at each stage of screening—first, the title/abstract screen then the full paper review (see box 2 and figure 1 (PRISMA flow diagram)).

Data extraction was performed by four members of the research team (S.N.W., J.J., J.K.W. and K.D.) and summarized in a data extraction table, with each summary being checked for accuracy by one other team member. Disagreements or inconsistencies in extracted data were discussed as a research team and resolved by consensus. Studies were assessed for Risk of Bias (observational) or study quality (qualitative). For observational studies, we used ROBINS-I (Intervention) (a tool to evaluate the tendency for non-randomized studies to differ systematically from the results expected from a randomized trial, according to a number of domains, including participant selection, confounding, measurement etc.) [24] (It should be noted that communication as an intervention does not lend itself as well to assessment using ROBINS-I as other NPIs, and so RoB categorizations should be treated with caution). For qualitative studies, we used the CASP (Critical Appraisal Skills Programme) checklist for qualitative studies (which includes 10 questions for assessing the validity of the method and results) [25]. Observational studies were initially graded for risk of bias, and qualitative studies for study quality, by one reviewer, with one other researcher checking for accuracy; issues or inconsistencies were discussed and resolved by consensus by the research team. Extracted data were reviewed and a narrative synthesis was performed, following the approach set out by Popay *et al.* [26]. Guided by the review objectives (research questions) extracted data were analysed to draw out a number of key themes across studies.

3. Results

A total of 11 500 records were identified through the search strategy. Following the removal of duplicates, 8838 records were screened for eligibility using study titles and abstracts. The full texts of 212 studies were then assessed for eligibility. Thirteen papers were included in the final sample (figure 1, PRISMA flow diagram).

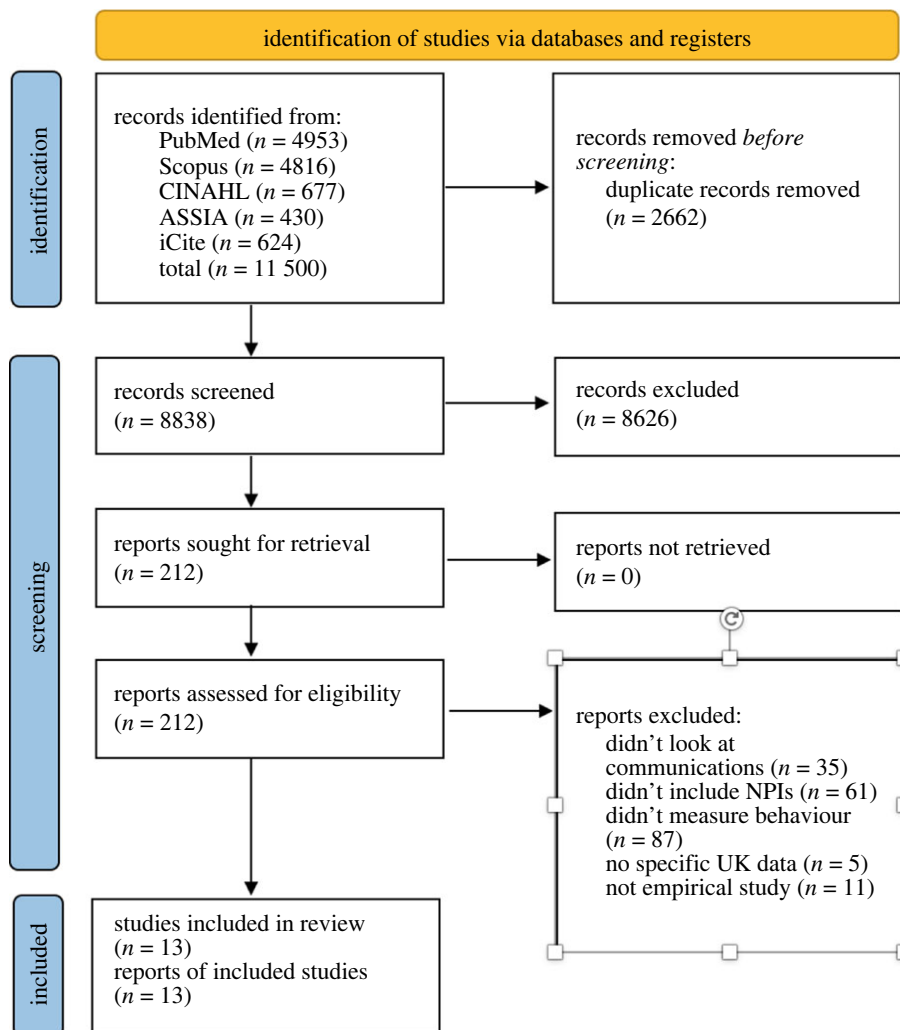

Figure 1. PRISMA 2020 Flow Diagram.

Overall, included studies were very heterogeneous in terms of their methods, objectives, content and focus (e.g. the types of communications explored and the types of NPIs included—see below). The 13 studies included zero randomized controlled trials (RCTs) or experimental studies; five observational studies (four cross-sectional survey; one longitudinal survey); seven qualitative studies and one mixed-method study (using cross-sectional survey and qualitative interviews). Table 1 summarizes the methods and findings of the studies included in the review.

Among the five observational (survey) studies, using ROBINS-I criteria, three studies were found to have serious risk of bias [28–30] (i.e. the study has important problems, relative to an RCT [24]) and two were found to have moderate risk of bias [27,31] (i.e. sound evidence for a non-randomized study but not comparable to an RCT [24]). Among the qualitative studies, all seven studies [32–38] were deemed high-quality qualitative studies according to CASP criteria.

Overall adherence was generally high. Eight studies [27–29,33,36–39] reported high adherence among participants, with a further two studies [30,31] reporting moderately high adherence. Three studies didn't provide data on levels of adherence per se, only factors related to adherence. For example, one study [27] found that over three-quarters (77.03–79.66%) engaged in one of the three health behaviours studied (hand washing, physical distancing and staying at home)

Table 1. Table summarizing studies selected to report on the effectiveness of communication on COVID-19 NPIs uptake or adherence.

reference	location	type of study	study scope	key findings related to communications and NPIs
Eraso & Hills [39]	UK	mixed-methods (qualitative and observational (cross-sectional))	psychosocial constructs/frameworks: trust (in government); COM-B Framework summary: study used online survey and interviews and regression analysis (quantitative) and framework analysis (qualitative) to explore factors associated with social distancing rule infringements study period: survey: 1–31 May 2020 interviews: 5 August–21 September 2020 sample: survey, $n = 681$ (female = 83%; White = 86%; mean age = 43); interviews, $n = 30$ (female = 47%; White = 63%; NPIs studied: social distancing (stay-at-home) communications types/sources: multiple psychosocial constructs/frameworks: trust (in government); perceived behavioural control (self-efficacy and controllability); theory of planned behaviour; the social ecological model	trust: an additional level of agreement on a 7-point Likert indicating trust in the Government decreases intentional s.d. infringements by 7.4% clarity and consistency: interview participants found government messaging to be confusing with some messages (e.g. 'stay alert) unclear or subject to interpretation. Interview participants also found messaging to be 'inconsistent' or 'contradictory'

Box 2. Inclusion and Exclusion criteria were used during the review.

Inclusion criteria, title/abstract screen; all criteria must be met for inclusion:

- English language studies
- reporting on COVID-19 alone, or COVID-19 and other respiratory infectious diseases
- reporting on communication as a method of increasing the uptake of, or adherence to, non-pharmaceutical interventions (NPIs) for COVID-19
- community-based setting (e.g. schools, daycares, residential settings, retail, restaurants, gyms and other athletic facilities, bars, workplaces, public parks, etc.)

Exclusion criteria, title/abstract screen; any one criterion is grounds for exclusion:

- non-English language studies
- does not report on COVID-19
- does not report on any NPI related to COVID-19
- any type of healthcare setting (e.g. long-term care, acute care, inpatient clinics, emergency department) are to be excluded; if relevant to our topic, they will be tagged according to setting for potential future use
- systematic reviews, narrative reviews and other evidence syntheses are to be excluded

Inclusion criteria, full-text screen:

- studies must report empirical data
- study designs: trials and experimental studies, including randomized and non-randomized designs; observational studies (cohort, case-control and cross-sectional studies); qualitative studies
- studies must include a focus on communication strategies or interventions to encourage adoption of or adherence to NPIs; i.e. studies must include focus on behaviour or action in relation to NPIs (not intention or attitudes to NPIs)
- studies must include data related to the United Kingdom (either as a case study or as a multi-country comparative study including the United Kingdom)

Exclusion criteria, full-text screen:

- studies focused on e-learning in general, not learning about COVID NPIs
- studies not related to uptake of/adherence to COVID behaviours/NPIs—including studies focused only on intentions, willingness or attitudes towards NPIs uptake/adherence
- studies not focused on communication (as an intervention or strategy—see definition above)
- studies focused on vaccination uptake
- studies not including the UK as an empirical case
- studies that discuss impact of NPIs on communication and interaction (e.g. facemasks, distancing on remote communication) (rather than vice-versa)
- studies focused on the psychosocial impact of NPIs and COVID communications (including media coverage)
- studies on telehealth or health-related communication between healthcare professionals and patients (not specifically related to COVID)
- studies that used communication media (e.g. Twitter analysis) to investigate something related to COVID-19 other than NPIs

and six in 10 (61.85%) engaged in all three. Studies found average self-rated adherence to be high across multiple protective behaviours, for example 4.36 on a 5-point scale (with 5 being 'several times per day' across all studied NPIs [29] or 6.29 on a 7-point scale, where 7 is 'very much so' following recommended behaviours). Qualitative studies that explored levels of adherence found perceived self-adherence to be high (if not necessarily perceived adherence by others) [36–39].

(a) What types of communication and communication strategies have been used to encourage non-pharmaceutical intervention adoption or adherence?

Overall, communication was studied or explored as one of a number of possible factors or variables predicting or impacting COVID-19 NPI adoption or adherence. Only one study focused exclusively on the effect of communication on NPI: a longitudinal (two waves of data) analysis explored how aspects of messages affected stay-at-home behaviour over time [31]. By their nature, qualitative studies tended to inductively explore themes (e.g. enablers and barriers) that explained adherence (or non-adherence) to NPIs (e.g. [33,35,38]). Of the five observational (survey) studies, two [27,28] looked at whether conspiracy theories predict NPI adherence, also looking at how conspiracy theories are influenced by communication (channels or sources). Two observational survey studies [29,30] and the one mixed-methods study [39] looked at general or multiple factors predicting NPI adherence, including communication.

Most studies looked at multiple communication channels (media) within one study, including traditional and social media and word-of-mouth communication (e.g. from friends, family and employers). One study [28] focused on public broadcast news (the BBC), and another focused on traditional media [29]. One study [35] explored focused on one form of communication—official communications sent out by programme implementers and stakeholders (e.g. universities and local government) to encourage engagement with COVID-19 testing interventions. Two studies [27,29] conducted separate analyses on specific forms of media (e.g. TV and newspapers). Most ($n = 8$) studies [27–29,33,34,36–38] looked at adherence to multiple NPIs (including, and especially in qualitative studies, generic 'protection measures'). One study [24] looked specifically at contact tracing app use. Two studies [31,39] looked specifically at quarantine (staying at home). Two studies [32,35] looked at engagement in community COVID-19 testing programs. Most studies looked at NPI adherence in the general UK public (but not with fully representative samples), with two studies focused on local or regional NPI adherence in England [32,35]. Two studies [34,35] focused on diverse ethnicities, and that tailored communication using targeted messages in multiple languages to specific ethnic communities was important for adherence. Very few studies focused on message content and framing. One study [31] specifically explored how aspects of messages related to time spent at home.

(b) What is the evidence for the effectiveness of communication strategies in non-pharmaceutical interventions adoption or adherence?

Among the observational studies, evidence of the effectiveness of communications on NPI uptake and adherence was mixed. Two studies [29,30] found that the communications studied had a positive effect on NPI adoption or adherence. One study [28] found no statistically significant effect—between conspiracy beliefs or news source and basic health-protective behaviours. Finally, two studies [27,31] found mixed effects of communication on NPI adoption and adherence. Among the qualitative studies, evidence of the effectiveness of communication on NPI adoption and adherence was also mixed. Two studies [33,39] discussed how communication served both as enablers and a barrier to adherence in their studies. For example, one study [39] found that government communication could have both positive and negative impacts on adherence. Four studies [32,34,36,38] identified only, or focused, on ways in which ineffective communication served as a barrier to adherence (or as a factor in non-adherence). Two studies [35,37]

Table 2. Principles for effective public health communication to influence health behaviour.

theme	findings summary	implication	studies
trust	low trust in government was associated with low adherence to behavioural public health interventions (NPIs)	information should be conveyed by trusted sources (e.g. health authorities)	$N = 10$ [23–25,27,29,31–35]
clarity and consistency	too many (often conflicting, unclear) messages were seen as a barrier to adherence (causing ‘alert fatigue’/information overload)	information should be conveyed clearly, and mixed messages should be avoided	$N = 9$ [25,27,29–35]
control	messaging focused on supporting autonomy, or being authoritative (but not inducing ‘control aversion’) was associated with higher adherence	communication should strike a balance between being authoritative but avoiding language seen as controlling (e.g. ‘you must’)	$N = 5$ [23,27–29,33]

identified only, or focused on, the ways in which effective communication served as enablers to adherence.

In terms of the effect of the type of media, two studies found that engagement with traditional media (e.g. TV and radio) was associated with greater adherence to NPIs [27,29], whereas one study found the use of social media to be associated with lower adherence to NPIs [27]. Two studies [28,30] found no statistically significant effect of news sources on adoption or adherence to NPIs. One found that official sources, including political parties and medical authorities led to higher use of a contact tracing app [30]. One study found that friends and family (word-of-mouth communication) had a small negative effect on adherence [27]. The main themes identified in this review, related to the characteristics of effective communication were clarity and consistency, trust and control. These are summarized in table 2.

(i) Clarity and consistency

The most common feature of effective communication identified was clarity and consistency. Overall, nine studies (one observational, seven qualitative and one mixed methods) [25,27,29–35] had findings which related to this theme. Six studies [29,32,33,37–39] identified message clarity and clear guidance as important. Five of these studies were qualitative, and so clarity of communication (or lack thereof), was defined by participants themselves (i.e. they perceptions of the how clear information was linked to adherence) [32,33,37–39]. One observational study measured quantitatively people’s ratings of clearness of information and ‘consistency of instructions and recommendations’ finding that these were significantly positively related to protective behaviours [29]. Four studies [29,33,36,38] identified consistent messages as being important. Studies suggested that participants felt ‘mixed messages’ [33,36], a lack of transparency [35] or inadequate communication of scientific uncertainty [34] led to confusion and in some cases non-adherence to COVID-19 guidance or rules. One study [36] found that too many, often conflicting, messages generated ‘alert fatigue’ or information overload and were seen as a barrier to adherence. Three studies [33,36,39] discussed how the communication of potentially ambiguous messages, rules and terms (e.g. ‘stay alert’ and ‘essential’) were open to interpretation and could therefore be a barrier to adherence.

(c) What evidence is there on the psychosocial determinants of non-pharmaceutical interventions adoption or adherence?

The evidence on psychosocial determinants was also heterogeneous, with studies using different psychological or behavioural constructs or frameworks. For example, two included studies specifically looked at the relationship between communication, conspiracy beliefs about the origins and spread of COVID-19 (e.g. that it was created or sanctioned by e.g. governments or the pharmaceutical industry) and NPIs. Findings were conflicting, with one study [28] finding that conspiracy beliefs were not statistically significantly associated with basic health-protective behaviours, but the other [27] found a strong negative relationship between conspiracy beliefs and engagement in all health-protective behaviours.

(i) Trust

The most common psychosocial factor was *trust*, being identified in 10 studies [28–30,33–39]. One prevalent theme ($n=6$ studies) was that low trust in government resulted in lower adherence to NPIs or protective behaviours [30,33,36,38,39] or to higher belief in conspiracy theories [28]. Conversely, higher trust in medical or health professionals or authorities was associated with higher adherence to NPIs [30,33]. Two studies [35,37] discussed the importance of generally ‘trusted’ or credible sources, for example to engagement in COVID testing [35] on parents’ adherence to various NPIs.

(ii) Control

Five studies explored the role of control on adherence [28,31,33,34,37]. Legate & Weinstein [31] provided the deepest treatment of the impact of control. Respondents were asked, during the first lockdown (March-May 2020), the extent to which they felt messages were controlling (e.g. ‘conveyed harsh legal consequences of not staying at home’) or autonomy supportive (e.g. ‘provided choices around how to make staying at home work for me’). The study found that autonomy-supportive messages, which framed the behaviour (staying at home) as being in line with individuals beliefs or values and which gave people a sense of choice, encouraged people to spend more time at home. Messages containing language perceived as ‘controlling’ (e.g. ‘you must’ and ‘you should’) were associated with less time spent at home. McNulty *et al.* [27] also discussed their findings in terms of the risks of poorly communicated rules leading to ‘control aversion’. However, whereas controlling language was seen as a potential barrier to adherence, authoritative communication—from sources perceived as official (e.g. national news, official government, or Prime Ministerial announcements) or including mandated messages (i.e. communicating legal requirements) predicted higher adherence to NPIs in three studies [29,31,37].

4. Discussion

Health communication, as a ‘meta-intervention’, plays an important role in the effectiveness of many, if not all NPIs, as well as the effectiveness of pharmaceutical interventions. It may, for example, help support the correct use of masks or reduce vaccine hesitancy. However, determining to what extent communication is effective in increasing the adoption of, or adherence to, NPIs, is challenging, for many reasons. Communication is itself a multi-faceted construct making it difficult to ‘isolate’ the impact of any one type or strategy of communication, and to disentangle communication from policy and law. This is especially the case in a public health emergency where rapidly changing information is being transmitted to the public about complex, evolving science, from numerous different sources. Indeed, ‘alert fatigue’ (information overload) has been identified as a barrier to adherence [36].

Notwithstanding these issues and difficulties, this review identified a small body of generally high-quality evidence, particularly obtained through qualitative studies, showing that communication was an important factor in NPI adherence and non-adherence. Overall, communication was good enough to ensure adherence to NPIs was high [3,4,27–29,33,36–39] although included studies also identify the characteristics that led to non- or less-rigorous adherence. This review provides additional evidence, using COVID-19 as a new example, of the importance of key features of effective communication in public health interventions: (i) *information should be conveyed clearly*, (ii) *conflicting (mixed) messages should be avoided*, (iii) *information should be conveyed by trusted sources* (e.g. health authorities) and (iv) *communication should strike a balance between being authoritative but avoiding language seen as controlling* (e.g. ‘you must’) (table 2).

Thus findings here serve to reinforce a large body of risk communication literature across public health (and from environmental health) which also emphasizes that clarity, consistency using trusted information sources and avoiding controlling language are key features of effective communication, designed to encourage adherence or behaviour change (e.g. [1,7,40–46]). Although these are not novel findings, it is a strength of this review, that existing findings usable from non-COVID research is borne out, since it helps to draw out generalizable principles usable for future public health crises.

At the same time, this review identified some limitations and omissions which raise additional questions that warrant further research. We draw out some of these key lessons and implications below. First, there is a need for more empirical research, particularly quantitative research that focuses specifically on communication, as an intervention or strategy. The studies meeting our inclusion criteria did provide useful insights into how communication can be effective, by ensuring it is clear and avoiding mixed messages, using trusted sources. However, a greater focus on communication as a facilitator or barrier to NPI adherence, also controlling for relevant confounders, allows a deeper analysis of some of the psychosocial determinants of its effectiveness (e.g. [31]).

There is a need for more studies that actually measure *behaviour* (e.g. the act of adhering) as an outcome, rather than intentions or willingness to adhere. However, there were a number of studies, some of which were well-designed (including RCTs or experimental studies) that were excluded because they only measured the impact of communication on intention or willingness to adopt or adhere to given NPIs. For example, one study found that after using an interactive web-based intervention participants subsequently reported intentions to increase their frequency of infection control behaviours [47]. Future reviews may seek to adopt a broader scope, looking also at the impact of communications on intentions—and perhaps also knowledge and attitudes—related to COVID-19. Nevertheless, while the study of intentions can help to support understanding of the motivations for behaviour, the inclusion of behavioural measures in future studies would further help to confirm these associations and bridge concerns about the intention-behaviour gap [48].

There is a need for longitudinal studies measuring the impacts of interventions on measured behaviour over different time points. This is important because it would help to determine which strategies and interventions have the most enduring impacts, as well as how people’s behaviour may change over different stages of a crisis. There may also be benefits to replicating the current review in future to explore whether those studies initially looking at behaviour were subsequently followed up to explore such issues as whether, and which, infection-reducing behaviours (e.g. mask wearing and hand hygiene) were sustained and for how long. Further, multi-method approaches should be adopted to ensure strong evidence on not only how people receive information but how they interpret it and why. For example, including the use of public/citizen panels that could provide real-time evidence of communication effectiveness.

Regarding the UK specifically, more research is needed on ethnicity, diversity and inclusion, such as how best to tailor communications specifically to ethnic minority groups in regard to encouraging and supporting engagement with NPIs. One of the key challenges here would be accounting for the role that cultural and political factors, including national, ethnic and

socio-political contexts, play in influencing all aspects of health risk communication (channels, sources, messages and audiences) [49]. Future evidence reviews might also seek to look at additional countries or take an international perspective to support these understandings.

In the UK, government leaders and spokespeople played a prominent role in regularly relaying information, advice and key announcements during the crisis [7]. Some studies have indicated that different leadership styles and strategies had a bearing on risk perceptions along with intentions to engage in safety-related behaviour in relation to COVID-19 for example [50]. However, this specific feature of pandemic communications did not figure as a primary focus of studies meeting criteria for inclusion in this review. Further research investigating the behavioural impacts of leadership communication is therefore warranted to support its use as a focal crisis response tool by officials.

This review highlights the importance of qualitative study findings in supporting research and policy understandings of the use and effectiveness of communication for NPI uptake and adherence. For example, it provided evidence that, from the perspectives of those receiving and interpreting guidance, the way it was communicated may have been insufficiently clear, overly complex or frequent, was perceived as inconsistent or conflicting [32,33,37–39]. However, the incorporation of advice arising from qualitative research evidence can sometimes meet policy resistance especially when viewed in relation to questions of ‘research bias’ and attention to the ‘hierarchy of evidence’ commonly attributed to randomized and controlled quantitative studies. This view can then limit the capacity of qualitative research to inform public health policies and practice. This review indicates that framing the contribution of studies in terms of ‘research quality’ is a useful way to bridge such concerns. It also highlights that the use of well-designed studies employing research panels to obtain qualitative data can offer valuable support to policy understandings of public perceptions (of both the risks and communication practices and impacts) as a crisis emerges and unfolds [51,52].

There were notably few studies that met all of our inclusion criteria, that is: which included a focus on communication (as an independent variable, predictor, mediator or factor); looked at behaviour (i.e. NPI uptake or adherence as a dependent variable or outcome); and which were based/focused on, or included data on the UK. As such there is an overall need for more research, especially RCTs or high-quality (low risk of bias) observational studies, which were otherwise found to be broadly lacking. This may be considered somewhat surprising given the unprecedented volume of research studies conducted in response to COVID-19 as well as the significant allocation of research funds made available through responsive calls in response to the crisis. In the event, besides the predilections of researchers to certain research frameworks and paradigms, many studies were understandably largely fragmented and designed and conducted at short notice in light of the emergency and thereby often limited in focus. Notwithstanding that there are many studies undertaken in response to the crisis yet to be published, this review indicates there is a need to develop ‘crisis ready’ research frameworks or protocols prior to future emergencies to ensure that the most pertinent knowledge is rigorously obtained.

In conclusion, despite the limited volume of evidence, and the need for more higher quality research in future, the studies included in this review suggest that health risk communication can have significant or important impacts on adoption of or adherence to public health behavioural interventions, with more effective communication shaped by the type, clarity and framing of the message and the messenger and communication channels used. Although findings from this review are specifically drawn from the UK, some of its key lessons and implications may be of broader relevance, specifically: the need for clear, consistent and trustworthy communication as facilitators to NPI adherence and the need to develop rigorous and comprehensive behaviourally focused research protocols in advance of future public health challenges. Put simply, poor communication can negatively affect adherence to public health behavioural interventions, whereas good communication can positively affect it.

Data accessibility. This is an evidence review of publicly available previously published studies. The data are provided in the electronic supplementary material [53].

All authors gave final approval for publication and agreed to be held accountable for the work performed therein.

Conflict of interest declaration. We declare we have no competing interests.

Funding. This research was funded by the Royal Society as part of its commissioned evidence reviews on the effectiveness of COVID-19 non-pharmaceutical interventions (NPIs).

Acknowledgements. We thank Professor Sir Mark Walport, Elizabeth Surkovic, Kyle Bennett and colleagues at the Royal Society for their guidance and support of this project, as well as colleagues across the Royal Society's programme of evidence reviews on COVID-19 non-pharmaceutical interventions. We would like to thank Professor James Rubin, Professor Christopher Armitage and Dr Tracy Epton for their helpful feedback on the design of the review. We also thank Swansea University Library staff for their assistance in the design of the search strategy used in this review. We also thank the five peer reviewers for their invaluable comment. All of the above have helped strengthen the final review.
