Abyssal seafloor communities cover more than 60% of Earth's surface. Despite their great size, abyssal plains extend across modest environmental gradients compared to other marine ecosystems. However, little is known about the patterns and processes regulating biodiversity or potentially delimiting biogeographical boundaries at regional scales in the abyss. Improved macroecological understanding of remote abyssal environments is urgent as threats of widespread anthropogenic disturbance grow in the deep ocean. Here, we use a new, basin-scale dataset to show the existence of clear regional zonation in abyssal communities across the 5,000 km span of the Clarion–Clipperton Zone (northeast Pacific), an area targeted for deep-sea mining. We found two pronounced biogeographic provinces, deep and shallow-abyssal, separated by a transition zone between 4,300 and 4,800 m depth. Surprisingly, species richness was maintained across this boundary by phylum-level taxonomic replacements. These regional transitions are probably related to calcium carbonate saturation boundaries as taxa dependent on calcium carbonate structures, such as shelled molluscs, appear restricted to the shallower province. Our results suggest geochemical and climatic forcing on distributions of abyssal populations over large spatial scales and provide a potential paradigm for deep-sea macroecology, opening a new basis for regional-scale biodiversity research and conservation strategies in Earth's largest biome.

The abyssal seabed lies between water depths of 3,000 and 6,000 m (ref. 1), representing most of the Earth's surface and harbouring some of its most extensive but least explored ecosystems. This abyssal seabed consists of plains and hills that extend across ocean basins,

interspersed with seamounts and subdivided by mid-ocean ridges, ocean trenches and fracture zones¹. Lacking sunlight, energy in this environment is highly limited, with detrital particles sinking from surface waters providing the main source of food², while temperatures

are steady at 0.5–3.0 °C (ref. 3) and bottom currents are generally low (0–0.25 m s⁻¹) (ref. 4). As a result, abyssal benthic communities typically exhibit low abundance and biomass compared with other marine environments⁵ but they support high species richness at regional to landscape scales^{6,7} and play an active role in the cycling of carbon⁸. Abyssal habitats are therefore considered to be reservoirs for biodiversity^{7,9} and sources of important ecosystem services^{2,10}. Despite their remoteness and as a consequence of being energy-restricted and environmentally stable, abyssal habitats are also expected to be highly vulnerable to anthropogenic disturbances including climate change^{11,12} and emerging industrial activities such as polymetallic nodule mining^{13,14}. To adequately conserve the biodiversity and services of abyssal seabed ecosystems, it is critical to consider and protect their full range of habitats and communities, which requires elucidating the patterns and processes controlling the distribution of abyssal populations over large, regional scales.

Macroecological studies assessing spatial variation on regional to global scales in the deep ocean^{15–18} have revealed that faunal body size and abundance gradually decline with decreasing energy availability along gradients such as increasing depth^{5,19} or latitude^{16,20}. These relationships are thought to constrain higher-order community structure and function²¹, for example, reducing the diversity of larger-sized taxa with depth²². Predicted declines in species richness with depth are consistent with checklist-based analyses of large marine databases²³. Overall, results from large-scale studies in the deep ocean confirm clear variation between abyssal and (shallower) bathyal seafloor ecosystems^{16,19,22}, which encompass a variety of relatively well-known habitats, between 1,000 and 3,000 m depth, including continental slopes, submarine canyons and coral mounds. Consequently, while biogeographic provinces proposed for the deep ocean readily distinguish bathyal and abyssal provinces within oceanic basins²⁴, potential variation within abyssal regions remains largely unresolved a decade after provincial boundaries based on surrogate environmental data were postulated²⁴, since large-scale empirical studies (for example, bottom-up assessments) are lacking for remote abyssal ecosystems. As such, the processes regulating alpha- and beta-diversity across the scale of a seemingly connected abyssal plain remain unclear, particularly for the largest size-class of seafloor organisms, megafauna (animals >10 mm in maximum dimension). Megafauna are a conspicuous component of the abyssal benthos and a common target for investigation in deep-sea spatial ecology^{13,25–27} because occurrences of these taxa can be determined across large spatial scales from seabed imagery²⁸ collected by deep-sea robots²⁹.

To address these knowledge gaps, we compiled a new basin-scale standardized dataset to investigate patterns of abundance and diversity in benthic megafaunal communities across the Clarion–Clipperton Zone (CCZ, northeast Pacific). The CCZ spans ~6 million km² of abyssal plain in areas beyond national jurisdiction between the Exclusive Economic Zones of Kiribati and Mexico (Fig. 1a) and is the largest area in the world currently in exploration phase for mineral mining^{30,31}. We selected data from 12 expeditions using comparable seabed imaging approaches to study invertebrate benthic megafauna distribution patterns across the CCZ. We collated, reanalysed, aligned and taxonomically standardized seabed imagery data from these studies including three new sites covering a total of >150,000 m² of seabed, which represents an area two orders of magnitude greater than that commonly assessed in studies of abyssal megafauna (for example, ref. 27,32, <5,000 m²). Our dataset spans 5,000 km across the CCZ (28 geographical locations) encompassing >50,000 megafaunal specimens from 411 morphotypes (morphologically identifiable taxonomic units³³) in 13 phyla, enabling investigation of ecological gradients (for example, with latitude, depth or food supply) in seabed communities across the region to develop key understanding of macroecological patterns in Earth's largest biome.

Results and discussion

Macroecological patterns in the northeast Pacific abyss

Our analyses reveal the existence of a clear depth zonation demarcating an evident boundary between biogeographic provinces across the northeast Pacific, with distinct shallow and deep-abyssal faunas and an intermediate transition zone. Regional benthic community structure at higher taxonomic levels exhibited a more pronounced relationship to depth (Fig. 2b) than other environmental gradients (for example, Supplementary Fig. 1) while food particle supply appears to be important at more intermediate, sub-regional, spatial scales (see below). Our results show distinct communities but incomplete taxonomic replacement in the presence and relative abundance of seabed taxa across the depth range studied, both within and between phyla. The most remarkable shifts were as follows: (1) soft corals (Alcyonacea) numerically dominated at shallow-abyssal depths (mean density ~2,500 individuals ha⁻¹) but decreased in abundance by over an order of magnitude below 4,300 m (mean density ~100 ind ha⁻¹), becoming virtually absent below 4,800 m (mean density <10 ind ha⁻¹); (2) brittle stars (Ophiuroidea) were most abundant at shallow-abyssal depths (mean density ~2,000 ind ha⁻¹), numerically dominated assemblages at intermediate depths (4,300–4,800 m; mean density ~1,500 ind ha⁻¹) but decreased to low abundances below 4,800 m (mean density <40 ind ha⁻¹); (3) anemones (Actiniaria) consistently increased in relative abundance with depth, first replacing soft corals as the dominant Cnidaria group below 4,300 m and then replacing brittle stars as the most dominant group in assemblages below 4,800 m (Fig. 2d); (4) sea cucumbers (Holothuroidea) largely increased in relative abundance with depth, replacing brittle stars as the most abundant Echinodermata group below 4,800 m (Fig. 2d); (5) shelled molluscs (for example, Bivalvia, Gastropoda and Polyplacophora), relatively abundant above 4,400 m (mean density ~300 ind ha⁻¹), were absent below 4,400 m, where cirrate octopuses (Cephalopoda) became the only molluscan group in megabenthic assemblages. Changes in dominant taxa at the class or phylum level (Fig. 2c) clearly delimited two distinct abyssal assemblages (Fig. 2d): a shallow community (3,800–4,300 m) and a deep community (4,800–5,300 m). These were separated by an intermediate or transitional assemblage (4,300–4,800 m), which contained elements of both communities. No major taxonomic groups were restricted to the transitional zone (Fig. 2c).

The zonation pattern was also evident at lower taxonomic levels in the 411 invertebrate morphotypes recognized in the data. For example, from the 277 morphotypes found in the deep province, 60 (41 rare, that is <5 occurrences) were found exclusively in this deep zone, while 64 morphotypes (45 rare) out of a total of 283 were found exclusively in the shallow province. However, only 25 morphotypes (23 rare) from a total of 264 were found exclusively in the transitional zone. From the total of 175 (14 rare) morphotypes that were found in both shallow and deep communities, only two were within the ten most dominant taxa in both the shallow province (first- and third-most abundant) and in the deep province (ninth- and tenth-most abundant; Supplementary Table 2): the brittle star *Ophiophthalma glabrum* (Fig. 1h; well-studied in the eastern CCZ³⁴) and *Thenea* sp. indet. (Fig. 1g), an undescribed species of nodule-dwelling sponge.

The nature of the taxonomic shifts between provinces and the depth range at which these occur suggests that the carbonate compensation depth (CCD) plays a key role in the depth zonation we encountered. The CCD lies close to the seafloor depth in the northeast Pacific³⁵, deepening north to south from ~4,400 to ~4,800 m (ref. 36). Below the CCD, calcium carbonate (CaCO₃) is undersaturated, which can energetically constrain the development and distribution of species highly dependent on carbonate structures such as in calcareous Foraminifera, a ubiquitous protozoan group showing clear depth zonation at intermediate scales in the abyss^{37,38}. It is these groups, probably depending on CaCO₃ structures, that exhibit the greatest variation in relative abundance or even presence with depth in our

analysis and thereby contribute most to regional beta-diversity. For example, shelled molluscs (requiring biomineralization of CaCO_3 for shell development³⁹) were absent below 4,400 m and soft corals (with scleroblast cells requiring CaCO_3 to produce sclerites⁴⁰) and bryozoans (most species dependent on CaCO_3 exoskeletons⁴¹) were replaced by ‘soft’ anemones (Actiniaria) below 4,300 m. The echinoderm transition from ophiuroids to holothurians below 4,800 m, yielding the dominant taxon of the deep province, could be related to either differing CaCO_3 requirements or metabolic efficiency, documented across echinoderms⁴². All of these shifts were observed within the depth range (4,400–4,800 m) of the CCD in the northeast Pacific^{35,36}. However, our understanding of biogeochemical and metabolic cycles in abyssal ecosystems is still too limited to fully comprehend the specific role of the CCD and calcium calcite saturation, as a biogeographical driver in abyssal metazoans.

Remarkably, despite the shifts in benthic community structure between provinces, diversity rates were relatively similar across biogeographic boundaries (Fig. 3c). Richness (Hill's $q = 0$) ranged between 32 and 62 morphotypes per 200 specimens in the shallow-abyssal province and between 48 and 63 in the deep one but we found no evidence of a difference in richness across the three depth ranges (overlapping 95% confidence intervals; Fig. 3c). We also found little evidence of variations between deep, transition and shallow assemblages in Shannon diversity (Hill's $q = 1$; Fig. 3e), a metric more sensitive to species evenness⁴³. However, we found very strong evidence of an increase in both taxa richness ($F_{1,159} = 115.4, P < 0.001$) and Shannon diversity ($F_{1,159} = 94.09, P < 0.001$) with increasing depth (Fig. 3d,f). This reflects a higher evenness of taxa in the deep province. For instance, the ten most abundant morphotypes in the shallow and intermediate depth ranges encompassed ~60% of the total abundance sampled in these areas, whereas below 4,800 m, the ten most abundant taxa represented only ~40% of all fauna (Supplementary Table 2). An increase in evenness across ecological communities is often related to a decrease in surface productivity⁴⁴ and, in abyssal areas, greater flux of sinking food is usually found in shallower locations nearer to surface primary production^{2,8}. This is generally the case in the northeast Pacific region⁴⁵ and seems a plausible driver for the higher evenness observed at regional scale in the deep province, particularly as our sampling approach was specimen-rarefied. The higher evenness of the deep community was also evident in species accumulation patterns (that is, steeper initial accumulation; Fig. 3g). However, with increasing sampling effort, estimated total richness of the deep province remained consistently higher than the shallower communities, suggesting that both biodiversity components (richness

and evenness) were not only maintained but slightly enhanced, with increasing depth.

Our results distinguish two abyssal biogeographic provinces with remarkably distinct benthic community features within a region (northeast Pacific) where a previous top-down environmental assessment identified the potential for two abyssal provinces²⁴. We found very strong evidence of different faunal densities between the deep and the shallow provinces (Fig. 3a), with megabenthic standing stocks largely decreasing with depth ($F_{1,82} = 51.61, P < 0.001$, Fig. 3b). As was expected from local megafaunal studies^{25–27}, density (range 0.06–1.46 ind m^{-2}) was up to an order of magnitude larger in the shallow than in the deep province (Fig. 3a). Nonetheless, regional patterns of density within provinces appeared more related to variations in food supply, that is particulate organic carbon (POC) flux, to the seabed (Supplementary Fig. 3a) than depth (Fig. 3b), especially in deposit-feeding fauna

Fig. 1 | Study region in the northeast Pacific basin and examples of abyssal benthic megafauna typically encountered at different depth ranges.

a, Map of study locations surveyed using deep-sea robots (ROVs and AUVs). Points indicate locations (depths 3,900–5,300 m) where data from seabed imagery studies were collated and reanalysed using standardized methodology for homogenous detectability and taxonomic identification of invertebrate benthic megafauna (animals >10 mm). The colour of the points follows a consistent scheme used to differentiate each site in the other figures. **b–p**, Examples of abyssal Pacific metazoan megafauna morphotypes (including depth, site and code in standardized catalogue), ordered by depth. **b**, *Relicanthus daphneae* sp. inc. Fig. 2 | Variations in the taxonomic composition of invertebrate megafaunal communities demarking biogeographic provinces within the northeast Pacific abyss. a, b, Two-dimensional representation of multidimensional scaling analyses, depicting assemblage Bray–Curtis dissimilarity rates (distance) calculated between 161 independent community samples (containing 200 specimens identified to morphotype level per sample) across 28 geographical locations. **a, b,** Sample point colour coding: study site of each sample location (**a**) or mean depth at sample location (**b**). Arrow depicting the spatial extent of the carbonate compensation depth (CCD) across the northeast Pacific. Isotropic contour lines (fitted using GAMs) represent rough approximates of depth-range bins to aid visualization of patterns. **c,** Ridgeline plots outlining the geometric

distribution of total abundance along depth for the dominant taxonomic groups in the abyssal CCZ megabenthos. On the y axis, frequency distribution relative to all the specimen occurrences sampled per group; colour, depth range (as depicted in **b**). **d,** Top four dominant taxonomic groups within the communities of different depth ranges (background seabed illustrating depth variation exaggerated across the region). ACT, Actiniaria; HOL, Holothuroidea; HEX, Hexactinellida; ANT, Antipatharia; ALC, Alcyonacea; OPH, Ophiuroidea; BRY, Bryozoa; and DEM, Demospongia. Note that depth was plotted decreasing from left to right, that is, west to east, to mirror the approximate spatial pattern across the CCZ.

(Supplementary Fig. 3b). In particular, the high variability in faunal density across the shallow province (Fig. 3a) probably reflects a latitudinal gradient in POC flux at intermediate scales, with lowest faunal densities in the northern sector (for example, range APEI-6 site: 0.3–0.4 ind m⁻²), increasing towards southeast locations (for example, ranges NORI-D, 0.9–1.2 ind m⁻²; APEI-12, 1.3–1.5 ind m⁻²) in closer proximity to the high primary productivity related to equatorial upwelling⁸, with known capacity to regulate abyssal benthic processes⁴⁶. Similarly, the benthic communities surveyed in northeasternmost locations (for example, APEI-6; ref. 47)—for instance, with the largest densities we observed in scavenging megafauna (mostly decapods and isopods; Supplementary Fig. 3d) and an evidently lower total taxonomic richness (Fig. 3h)—were markedly distinct from those in the southeast locations of the shallow province (such as BGR-E, UK-1, APEI-12 and NORI-D; Fig. 2a and Supplementary Fig. 2). These differences could be driven by altered oceanographic conditions over the northeast CCZ, potentially related to the influence of the North Pacific Equatorial Current⁴⁸ and the closer proximity to the continental shelf, which may transport pelagic food falls⁴⁹ more commonly into this sector. Hence, while regional patterns across provinces in abundance, diversity and community composition

were clearly zoned by depth over scales of thousands of kilometres, variations at intermediate scales within provinces, over hundreds of kilometres, might be more related to surface productivity gradients³² (also at the deep province; for example, Supplementary Fig. 2c) and other environmental (hydrographical) variation between sectors. Overall, this reflects a much higher ecological heterogeneity, at multiple scales, than was previously expected for benthic assemblages across the northeast Pacific abyssal seabed. This overlooked heterogeneity, stemming from geochemical and climatic forcing, has crucial implications for future ecological and macroecological research in abyssal communities and for the success of regional-scale conservation strategies implemented to protect biodiversity in the CCZ⁵⁰ and probably in other abyssal areas targeted by deep-sea mining worldwide³¹.

Conclusions

The results of this study represent the largest multiphyllum assessment of beta-diversity patterns to date conducted across such a vast abyssal seabed extension (>5,000 km span), provide key insights to our view of abyssal ecosystems and biodiversity and challenge some current paradigms in deep-sea macroecology. The maintenance

of high taxonomic richness with increasing depth by phylum-level replacements (in presence or dominance) was surprising. Diversity, especially that of the largest-sized fauna, is commonly expected to decrease with depth and nutrient flux in the deep sea^{5,19,21,22}, a reduction that is thought to reflect the wider geographic ranges of deep-sea species²³. But our results suggest that more complex processes may control diversity in the abyss, helping maintain community richness with depth. These interpretations could be affected by the historical unbalance in the sampling conducted in abyssal ecosystems (for example, ~90% of the species living at the CCZ remain undescribed⁵¹) compared to shallower deep-sea environments⁵². In turn, our results add to the existing evidence⁵³ against a source–sink dependency from bathyal to abyssal communities in the Pacific⁵⁴ and stress that, given the wealth of between-phylum species replacement we encountered with increasing depth, assessments including multiple phyla might be best suited to investigate biodiversity and macroecological patterns in abyssal regions.

The presence of such a clear and unexpected boundary zone demarking the limits of provinces has not been previously documented in abyssal metazoans, opening questions for further macroecological research in the deep ocean. We suggest that the CCD may control the location of the environmental boundaries between shallow and deep-abyssal provinces for megafauna, as appears to occur in protozoans (for example, Foraminifera^{37,38}), although more physiological research is needed to better understand how CaCO₃ saturation affects different phyla. Greater understanding of CaCO₃ saturation as a biodiversity driver is especially important as the CCD is expected to shoal with increased CO₂ levels in the ocean associated with climate change⁵⁵. In the light of our results, shoaling of the CCD could have much larger implications for abyssal biodiversity than previously expected, especially in regions like the northeast Pacific where the seafloor depths transcend the current CCD¹¹. A CCD shoaling of tens of metres in abyssal ecosystems, given their vast area, could lead to shifts in the environmental conditions (for example, from CaCO₃ saturation to undersaturation) across thousands of km² of seabed worldwide. This could trigger large shifts in community structure and species distributions or even extinctions of highly specialized abyssal taxa, adding to the cumulative impacts of deep-sea mining and other emerging anthropogenic disturbances⁵⁶ that might concur on Earth's largest biome in the coming years.

Fig. 3 | Standing stocks were substantially larger in the shallow than in the deep-abyssal province while biodiversity rates were similar, although slightly increasing with depth, across the northeast Pacific abyss.

Methods

Study area

The CCZ is an extensive abyssal plain and hill ecosystem, interspersed by seamount areas^{26,57}, covering approximately 6 million km² of seafloor stretching from 5° to 20° N and 115° to 160° W in the northeast Pacific basin (Fig. 1). Important abiotic factors are broadly similar across the northeast Pacific abyssal seafloor, such as low currents, constant bottom-water salinity and temperature⁴⁵. In contrast, there is a gradual increase in water depth from east to west (from 3,700 to 5,500 m; Fig. 1a) resulting from the contraction of older oceanic crust to the west⁵⁸ and a gradient in POC flux to the seabed, generally diminished with depth but largely enhanced towards more productive southeastern waters⁵⁹ (Supplementary Methods). In turn, the CCD (the depth below which the rate of supply of calcium carbonate from the

surface is equal to the rate of dissolution⁶⁰) lies close to the seafloor in the northeast Pacific³⁵, deepening north to south between 4,400 and 4,800 m (ref. 36). Surface sediments in the northeast Pacific are relatively well-oxygenated and generally dominated by either siliciclastic clay and radiolarian ooze in the northern and central parts of the CCZ, or by biogenic calcareous oozes and fine-grained sediments in southern sites⁴⁵. These are supplied by extremely low sedimentation rates, regionally varying between 0.2 and 1.15 cm per 1,000 years⁶¹. These conditions are thought to promote the (extremely slow) formation of polymetallic nodules³⁵, yielding growth rates of ~1–12 mm per million years in the abyssal Pacific³¹. Nodules can vary in size, shape and abundance⁶¹ and are extensively distributed across the northeast Pacific³¹ but are not exclusively found there. Vast abyssal nodule field areas are present in the southeast Pacific (for example, Peru Basin), the southwest Pacific (for example, Penrhyn Basin) and in the Central Indian Ocean Basin³¹. Nodule fields form an unusual mosaic habitat, where the hard substratum provided by nodules acts as keystone structure increasing local seabed complexity^{62,63}, promoting the occurrence of some of some of the most biodiverse benthic assemblages surveyed in the abyss^{25,27}. But the biodiversity of the CCZ is poorly known, for example 90% of the species identified in the region are thought to be new to science⁵¹ and substantial levels of dark biodiversity have been predicted³⁴. In addition, a general lack of standardization of intercalibrated taxonomic standards for the identification of benthic fauna⁵⁰ has historically hampered comparability between biological studies⁶⁴ and thereby the assessment of regional, macroecological patterns across the northeast Pacific basin.

Data processing

Occurrences of benthic invertebrate metazoans were collated from a range of seabed image surveys collected using comparable sampling methodology across the northeast Pacific (Table 1). To ensure homogeneous animal detectability and a minimum sample size per study location, we selected only available imagery obtained using deep-sea robots (remotely operated vehicles, ROVs; and autonomous underwater vehicles, AUVs; and towed-camera platforms) that fulfilled the following criteria: (1) collected between 1 and 4 m above the seabed; (2) well-lit and high resolution (that is, minimum resolution at 2 m above-seabed, 1,280 × 720 pixels); (3) total seabed survey area imaged per location >2,000 m²; (4) no overlapping frames included in image-based studies; (5) scalable stills collected vertically facing the seabed (only in data used for density analysis, see below). Imagery data were collected within 14 sites managed by the International Seabed Authority across the CCZ (Table 1 and Fig. 1a); eight mining exploration-licensed sites and six APEIs.

Mega fauna specimens >10 mm were detected and counted in imagery reanalysed from the selected surveys (Table 1). Using BIIGLE 2.0 software⁶⁵, animals were identified to the lowest taxonomic level possible (morphotype, typically genus or family level in undescribed species; for example, Fig. 1b–p) in accordance with an abyssal-Pacific standardized mega fauna catalogue⁶⁶ developed during a range of scientific workshops, in collaboration with taxonomic experts (see Acknowledgements), and by reference to existing literature^{67–69}—though developed before the major higher taxonomic revision recently undergone by Octocorallia⁷⁰. The catalogue follows the ref. 33 open nomenclature to report the taxonomic resolution reached in each morphotype but all taxa identified from the catalogue (411 morphotypes in this study) were deemed as sufficiently different morphologically by taxonomic experts to be confidently considered separate species. Specimens with uncertain classification at the morphotype level (~30% of all records) but identifiable to a certain higher taxonomical level (like phylum or class) were retained only for density analyses. Taxa living in a closed shell or tube (for example, most polychaetes) were excluded from analysis as it is not possible to determine whether these are alive in images. Several spatially blind reviews were

Table 1 | Seabed imagery data collected across northeast Pacific basin (order west to east) and selected for standardized analysis in the present study. Note that video datasets with high uncertainty of the estimated area surveyed were not used in density analyses and ‘Area sampled’ provided as approximate total linear length of survey transects

^aDatasets excluded from density analyses. ^bCollection methodology provided in Supplementary Methods.

conducted to the whole dataset to ensure a robust taxonomic alignment between sites, consisting in side-by-side visualization of all specimens classified under the same catalogue label using the ‘Label Review Grid Overview’ tool in BIIGLE⁶⁵; a process that was repeated many times by the same group of expert seabed image scientists, to minimize potential bias²⁸. In addition, the likely feeding behaviour (suspension, deposit and scavenger or predator feeding) of each morphotype was inferred from observational knowledge and by reference to similar organisms described in the literature. With a total of 53,512 megafaunal specimens in 13 phyla, our biodiversity dataset was compiled across a wide geographical span (>5,000 km) at the abyss and is of comparable magnitude to the largest datasets that have been used to underpin our theoretical understanding in the deep-sea (for example, refs. 71,72).

Survey design

We compiled invertebrate mega fauna occurrences into two different subsets to investigate variations across space in different parameters. These were (1) standing stocks subset (SSdat): containing faunal count data at all taxonomical levels obtained only from scalable still images and thereby associated with a precise measure of the seabed surface area (47,087 specimens); and (2) biodiversity subset (BDdat): containing faunal count data obtained from both image and video surveys but including only specimens identified up to morphotype level (36,432 specimens). Using ArcMap v.6.10 software, we interpolated each specimen across a 10 × 10 km² regional grid to assign and constrain occurrence data to different geographical locations (units of 100 km²) within sites. This process divided the SSdat into 23 locations and the BDdat into 28 locations (Fig. 1 and Table 1). Faunal occurrences (or image units, in SSdat) within each geographical location were then randomly resampled without replacement to generate equally sized (in terms of number of specimens encountered) replicate sample units, characterizing the community at each location while

minimizing potential spatial autocorrelation biases (for example, ref. 73). In locations where surveys covered a large depth spectrum, data were further constrained to 200 m depth bins during replicate sample generation. Following recommendations of minimum sample size for accurate and precise estimation of local megabenthic community features⁴⁷ and to minimize the potential effect of regional gradients in faunal abundance on diversity measures (for example, ref. 25), we generated SSdat samples containing 450–500 specimens (taxonomic resolution including specimens identified to morphotype and to higher taxonomical levels) and BDdat samples containing an exact number of 200 specimens (taxonomic resolution including only specimens identified to morphotype level). This process yielded a total of 84 samples standardized for density analyses (standing stocks) and 161 samples standardized for biodiversity analyses (richness and beta-diversity).

Data analysis

Depth and position (latitude and longitude) of specimens (or images) were averaged within each sample to investigate variations in communities across space and environmental gradients. Sample positions were interpolated with predictions of yearly POC flux ($\text{gC}_{\text{org}} \text{m}^{-2} \text{yr}^{-1}$) to the seabed derived by applying vertical flux attenuation⁵⁹ to satellite-derived export flux data (Supplementary Methods). Different ecological metrics were calculated for each sample: (1) standing stocks were assessed as the total numerical abundance of specimens per total unit (m^2) of seabed surveyed in each SSdat sample; that is, for the whole assemblage, specific populations or faunal groups of interest (taxonomic or functional) and (2) to examine the range of diversity characteristics, Hill's diversity numbers of order 0 and 1 (ref. 43) were calculated in each BDdat sample as morphotype richness (S), the exponential form of the Shannon diversity index ($\exp H'$), for the whole assemblage.

Preliminary exploration of the interaction between different environmental factors (depth, latitude, longitude and POC flux) across study locations revealed substantial correlations between depth and longitude and also between POC flux and latitude (see Supplementary Fig. 1). Consequently, we choose to investigate only potential interactions between ecological metrics (y , that is standing stock and diversity indices) and two main environmental factors (x , that is water depth and POC flux, as these were not significantly correlated; see Supplementary Fig. 1). We used the Akaike information criterion⁷⁴ to select the best fitting linear regression across a range of data transformation types (where 'exp' consistently outperformed 'linear' and 'log').

We followed a simple, data-driven, bottom-up approach to investigate the potential existence of biogeographic boundaries across the depth spectrum of the north Pacific abyss. First, using the whole dataset, we generated ridgeline plots depicting within-group geometric distributions of the total abundance sampled in the most dominant high taxonomic groups (>50 occurrences, minimum taxonomic rank: order). On the basis of the results of this analysis, we assessed the potential variability within and between the megabenthic communities in tentative biogeographical provinces, by grouping samples in three different depth bins: shallow <4,300 m; transition 4,300–4,800 m; deep >4,800 m. Mean values and 95% confidence intervals were calculated for different ecological parameters (faunal density based on SSdat samples and both diversity indices based on BDdat samples) within each tentative province. To contextualize patterns in morphotype richness and the representability of the sampling conducted within each depth range, morphotype accumulation curves were calculated following ref. 75, by random resampling of BDdat samples in each depth category 100 times without replacement forming increasingly larger sampling units, using EstimateS v.9.1 software⁷⁶. In addition, using the same methodology, curves were also calculated for study sites encompassing a minimum of three BDdat samples (sampling effort >600 specimens identified to morphotype level).

Variations in community composition across locations, sites and potential biogeographical provinces were further explored using BDdat samples. Dissimilarity in faunal composition between all pairs of samples was calculated using the Bray–Curtis dissimilarity measure on square-root transformed (normalized⁷⁷) taxon abundances. Non-metric multidimensional scaling ordinations were conducted to visualize the rate of dissimilarity (distance) between all pairs of samples; isotropic contour lines depicting broadly approximated depth ranges were fitted using generalized additive models⁷⁸ in the resulting multidimensional scaling plots to aid visualization of beta-diversity patterns across environmental gradients. All data processing and analysis were implemented in R v.4.2.1 (ref. 79), using standard analysis methods and functions from the packages: 'vegan'⁸⁰, 'AICcmodavg'⁸¹, 'ggrridges'⁸² and 'ggplots2'⁸³. We report statistical evidence of variations in ecological parameters across environmental gradients (linear regressions, that is R^2 and P values) or between biogeographical provinces (95% confidence intervals; significant at $P < 0.05$) using the simplified language of evidence⁸⁴.

Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

Data availability

Data generated for this study, invertebrate abyssal megafauna taxa occurrences across the northeast Pacific seafloor, are available at <https://doi.org/10.5281/zenodo.7982461> (ref. 85). The Abyssal Pacific Seafloor Megafauna Atlas (APSMa image-based taxonomical catalogue) developed to conduct this study is available at <https://doi.org/10.5281/zenodo.7765164> (ref. 66). Data handling and analyses were implemented using standard methods, software tools and code functions detailed in the Methods.

Reporting Summary

Nature Portfolio wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Portfolio policies, see our [Editorial Policies](#) and the [Editorial Policy Checklist](#).

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

n/a | Confirmed

- The exact sample size (n) for each experimental group/condition, given as a discrete number and unit of measurement
- A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
- The statistical test(s) used AND whether they are one- or two-sided
Only common tests should be described solely by name; describe more complex techniques in the Methods section.
- A description of all covariates tested
- A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
- A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
- For null hypothesis testing, the test statistic (e.g. F , t , r) with confidence intervals, effect sizes, degrees of freedom and P value noted
Give P values as exact values whenever suitable.
- For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
- For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
- Estimates of effect sizes (e.g. Cohen's d , Pearson's r), indicating how they were calculated

Our web collection on [statistics for biologists](#) contains articles on many of the points above.

Software and code

Policy information about [availability of computer code](#)

Data collection | ArcMap v.6.10 and BIIGLE v.2.0 used for image data handling

Data analysis | EstimateS ver .9.1
R ver 4.2.1
vegan package ver 2.6-2
AICcmodavg package ver 2.3-1
ggridges package ver 0.5.3
ggplots2 package ver 3.3.6

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors and reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Portfolio [guidelines for submitting code & software](#) for further information.

Data

Policy information about [availability of data](#)

All manuscripts must include a [data availability statement](#). This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A description of any restrictions on data availability
- For clinical datasets or third party data, please ensure that the statement adheres to our [policy](#)

Provide your data availability statement here.

Human research participants

Policy information about [studies involving human research participants and Sex and Gender in Research](#).

Reporting on sex and gender

Use the terms *sex* (biological attribute) and *gender* (shaped by social and cultural circumstances) carefully in order to avoid confusing both terms. Indicate if findings apply to only one sex or gender; describe whether sex and gender were considered in study design whether sex and/or gender was determined based on self-reporting or assigned and methods used. Provide in the source data disaggregated sex and gender data where this information has been collected, and consent has been obtained for sharing of individual-level data; provide overall numbers in this Reporting Summary. Please state if this information has not been collected. Report sex- and gender-based analyses where performed, justify reasons for lack of sex- and gender-based analysis.

Population characteristics

Describe the covariate-relevant population characteristics of the human research participants (e.g. age, genotypic information, past and current diagnosis and treatment categories). If you filled out the behavioural & social sciences study design questions and have nothing to add here, write "See above."

Recruitment

Describe how participants were recruited. Outline any potential self-selection bias or other biases that may be present and how these are likely to impact results.

Ethics oversight

Identify the organization(s) that approved the study protocol.

Note that full information on the approval of the study protocol must also be provided in the manuscript.

Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

Life sciences Behavioural & social sciences Ecological, evolutionary & environmental sciences

Ecological, evolutionary & environmental sciences study design

All studies must disclose on these points even when the disclosure is negative.

Study description

This study aims to determine if trends exist in the spatial distribution of abyssal seafloor populations, and which environmental controls might best explain such changes, for the first time at regional to intermediate scales, using a simple bottom-up analytical approach. To this purpose, invertebrate occurrences obtained from comparable seabed imagery collected in multiple locations (constrained to 10 x 10 km seabed patches) across the CCZ abyssal plain (N Pacific) were compiled from previous studies (including three previously unexplored sites) and reanalyzed using standardized methodology. Randomly generated replicate samples with fixed size (i.e. 200 specimens) were used to characterize and compare abundance, diversity and similarity between communities at different locations and whether these variations exhibited any trends depth of food supply.

Research sample

Invertebrate benthic megafauna (animals > 10 mm) occurrences (i.e. latitude, longitude, and depth) were obtained from detection and identification of these species by reanalysis of seabed imagery collected using comparable methods (e.g. high resolution video and stills cameras mounted on deep sea robots). The standardized methodology used, detailed in the methods, ensured homogeneous animal detectability and subsequent taxonomic identification; robustly aligned across all the images processed. This procedure yield to the identification and geo-referencing of >50,000 specimens (13 Phyla) across 28 geographical locations across the N Pacific abyssal seafloor.

Sampling strategy

Sampling strategy was based on standardized protocols for reliable characterization (i.e. min sample size: 200 morphotype-level-identified specimens per community sample) of abyssal benthic megafauna assemblages in seafloor spatial ecology by Simon-Lledo et al 2019a

Data collection

Seabed imagery were collected in multiple expeditions, but the study only used those image datasets that complied with the following conditions (aimed to ensure that image quality enabled a consistent specimen > 10 mm detectability throughout the

dataset): i) imagery collected between 1–4 m above the seabed; ii) well-lit and high resolution (i.e. minimum resolution at 2 m above-seabed: 1280 x 720 px); iii) total seabed survey area imaged per location >2000 square meters; iv) no overlapping frames included; v) scalable stills collected vertically-facing the seabed (for density analysis only); vi) collected in abyssal nodule field habitats within the CCZ

Timing and spatial scale	Specimen occurrence data were obtained during different deep-sea expeditions conducted between 2010 and 2020 across the 5000 km span of CCZ region
Data exclusions	Taxa living in a closed shell or tube (e.g. most polychaetes) were excluded from analyses as it is not possible to determine whether these are alive in images. Giant seabed foraminifera (Xenophyophores) were also excluded from analysis, for the same reason.
Reproducibility	The original dataset generated and used to run the analyses is provided as source data files, the software and standard code functions used are all open-sourced, and the taxonomic identification catalogue used to standardize specimen identifications is available on-line.
Randomization	Replicate seabed community samples of fixed size were generated by random selection (without replacement) of specimen occurrences falling within each spatially restricted (i.e. 10 x 10 km patch size) locations.
Blinding	We used BIIGLE 2.0 to blind the location of the images containing each of the specimen occurrences during image re-analysis to minimize potential observer-bias. Several spatially-blind reviews were conducted to the whole dataset to ensure a robust taxonomic alignment between data from different sites, consisting in side-by-side visualization of all specimens classified under the same catalogue label using the 'Label Review Grid Overview' tool in BIIGLE 2.0.

Did the study involve field work? Yes No

Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.

Materials & experimental systems
