Abstract

Field experiments were conducted on two coastal gravel barriers backed by freshwater lagoons to examine the groundwater dynamics and to investigate the potential for saline intrusion. At Slapton Sands, groundwater, lagoon and ocean water level data were collected over a one year period; at Low Bar, data were collected over a two week period. The groundwater table was highly dynamic at both sites, with the ocean tide and wave event signals propagating to within a few metres of the lagoons.

The amplitude and phase lag of the ocean tidal signal as it propagated landwards were used to apply the one-dimensional unsteady groundwater flow equation to estimate the hydraulic conductivity of the barrier aquifers. K is $O(0.01)$ m s⁻¹ at both field sites, and this was used with the measured hydraulic gradients to estimate the barrier discharge. Net discharge was directed seawards and strongly positively correlated with the lagoon elevation and large wave events. In contrast, discharge was only weakly correlated with ocean tidal range and lagged by 4 days. This is due to strong landward-directed hydraulic gradients during spring tides reducing the lagoon-derived freshwater flux, with peak discharge occurring mid-way between spring and neap tides. The shoreline of the lagoon was decoupled from the groundwater table at both sites. The groundwater elevation was 1–2 m lower, suggesting that seepage from the lagoon to barrier occurs through the base of the lagoon. This is of potential significance to the modelling of coastal gravel barriers.

Groundwater conductivity measurements demonstrated that salt water penetrates some distance landwards into the barriers (c. 60 m from spring high tide level). However, the width of the barrier systems (120 and 275 m) and the high water level of the fresh water lagoons, c. 0.75–2 m above spring tide level, inhibit saline intrusion.

Keywords: groundwater; gravel barrier; saline intrusion; field experiment; coastal

1. Introduction

Coastal aquifers are complex zones due to the combined influences of oceanic (waves and tides) oscillations and inland groundwater forcing. They are also of significant societal importance for, at least, two main reasons. Firstly, groundwater discharge from coastal aquifers can transport material (e.g. pollutants) from the land to the sea, often at much higher concentrations than in rivers (Windom and Niencheski, 2003). For example, nutrient enrichments of coastal waters has been attributed to groundwater input by a number of researchers and can significantly impact coastal ecosystems (Slomp and Cappellen, 2004; Rao and Charette, 2012). Secondly, saltwater intrusion, which is the ingress of salt water into coastal aquifers, is becoming increasingly widespread and may pose significant problems for agriculture, drinking water supply and fresh water ecosystems (e.g. Andersen et al., 2007). The key factors controlling these two processes are the gradient of the coastal water table and the hydraulic conductivity of the sediment matrix. Significant research efforts

33 have been expended over the past few decades to better understand and model coastal aquifer dynamics
 34 (for a recent overview, refer to special issue of Hydrogeology edited by [Post and Abarca \(2009\)](#)).

35 In coastal aquifers hydraulically connected to the sea, groundwater levels fluctuate with the rise and fall of
 36 the ocean tide, and also respond to offshore wave forcing ([Turner and Nielsen, 1997](#)). Typical characteristics
 37 of groundwater table fluctuations due to tidal effects include ([Nielsen, 1990](#); [Raubenheimer et al., 1999](#)): (1)
 38 asymmetric fluctuations with a rapid rise and slow fall; (2) a damped tidal water table fluctuation; and (3) a
 39 lag between ocean tidal signal and groundwater table signal. All three characteristics increase in a landward
 40 direction. The effect of waves is to pump sea water into the coastal aquifer due to wave runup. This results
 41 in a super-elevation of the coastal water table underneath the swash zone and this overheight is directly
 42 proportional to the wave height, and also dependent on the beach gradient and wave period ([Nielsen, 1990](#);
 43 [Masselink and Turner, 2012](#)).

44 The salinity structure in a tidally-influenced aquifer is also reasonably well-known and consists of a
 45 lower saltwater wedge and an upper saline plume ([Robinson et al., 2007, 2009](#); [Abarca and Clement, 2009](#)).
 46 The saltwater wedge occurs irrespective of wave/tidal action, but the saline plume is due to the tides and
 47 results from infiltration in the upper intertidal region, added to by wave action, and exfiltration in the lower
 48 intertidal zone. Freshwater exits around the low tide level, and the intense region of mixing between the
 49 upper saline plume and the freshwater outflow is known as the sub-terranean estuary ([Cooper Jr, 1959](#);
 50 [Robinson et al., 2006](#)). Mixing processes in the sub-terranean estuary are considered of great importance to
 51 the fate of contaminants and pollutants.

52 Measurements of the tide-induced groundwater level variations (specifically, the attenuation and time
 53 lag of the tidal groundwater signal) can offer important information on the aquifer properties, especially the
 54 transmissivity and the hydraulic conductivity (e.g. [Erskine, 1991](#); [Trefry and Johnston, 1998](#); [Corbett et al.,
 55 2000](#); [Zhou, 2008](#)). The approach generally used for this purpose is the solution to the one-dimensional
 56 unsteady groundwater flow model in a confined aquifer, which further assumes that the beach is vertical
 57 and that the aquifer is uniform. Strictly speaking this method is only applicable to confined aquifers, but
 58 it may also be used for unconfined aquifers if the amplitude of the tidal groundwater table fluctuations are
 59 small compared to the depth of an unconfined aquifer and if the observations are made sufficiently far from
 60 the intersection between the beach and the groundwater table ([Millham and Howes, 1995](#)).

61 The hydraulic head of the groundwater fluctuates with the tide, but with an amplitude attenuation and
 62 phase lag that increase moving landwards from the shoreline. Equation (1) is the standard solution to the
 63 one-dimensional unsteady groundwater flow model (e.g. [Fetter, 1988](#); [Todd, 1980](#)),

$$H(x, t) = H_0 \exp\left(-x\sqrt{\frac{\pi S}{t_0 T}}\right) \sin\left(\frac{2\pi t}{t_0} - x\sqrt{\frac{\pi S}{t_0 T}}\right) \quad (1)$$

64 where H is the hydraulic head of the aquifer (m), x is distance from the shoreline (m), t is time (d), H_0 is
 65 the tidal amplitude (m), t_0 is the tidal period (d), T is transmissivity ($\text{m}^2 \text{d}^{-1}$) and S is the specific yield of
 66 the aquifer (dimensionless). Fig. 1 defines the aquifers and water levels in the problem coordinate system
 67 for a typical coastal gravel barrier cross-section as observed on the southwest coast of the UK.

68 The amplitude of the water level fluctuations in a cross-shore transect $H(x)$, for example measured using
 69 a series of groundwater wells, is related to H_0 by the tidal efficiency factor (TE), described by the first term
 70 on the RHS of Equation (1):

$$TE = \exp\left(-x\sqrt{\frac{\pi S}{t_0 T}}\right). \quad (2)$$

71 Equation (2) shows that TE decreases exponentially with distance landwards and the damping constant β
 72 is described as:

$$\beta = \sqrt{\frac{\pi S}{t_0 T}}. \quad (3)$$

73 The temporal lag (t_L) in the arrival of the tidal signal at some distance landward of the shoreline is

74 described by a rearrangement of the second term on the RHS of Equation (1):

$$t_L = x \sqrt{\frac{t_0 S}{4\pi T}}. \quad (4)$$

75 Equation (4) shows that t_L increases linearly with x , and the slope a is described as:

$$a = \sqrt{\frac{t_0 S}{4\pi T}}. \quad (5)$$

76 Hydraulic conductivity K is a property of both the porous media and the flowing fluid and is calculated
77 from its relationship with T (Fetter, 1988):

$$T = Kb, \quad (6)$$

78 where b is the saturated aquifer thickness (m). The solution to Equation (1) via the tidal efficiency or
79 temporal lag is usually referred to as the the tidal damping method. It can be used to determine an
80 integrated estimate for the entire coastal region under consideration (usually a coastal barrier system) and
81 can therefore be more representative than spot measurements of aquifer properties, for example by means
82 of slug tests.

83 Saline intrusion is the flow of seawater into freshwater coastal areas such as wetlands, lagoons and
84 aquifers, where it can severely disrupt ecosystems (Boulton, 2005) or pollute water supplies (Barlow, 2003).
85 Saline intrusion has typically been observed in regions of groundwater extraction in the coastal zone for
86 potable water, irrigation and industrial uses (Barlow, 2003), but storm surges (Steyer et al., 2007), sea
87 level rise (Feseker, 2007) and water-level fluctuations are increasingly of concern. This is potentially of
88 great significance because many gravel barriers are backed by fresh water lagoon systems, often of high
89 conservation value. In such settings a very pertinent, and in light of anticipated sea-level rise and increased
90 storminess due to climate change increasingly relevant, question relates to the potential for saline intrusion
91 during spring high tides, especially if accompanied by storm surge and energetic wave action.

92 The rate and pathway of saline intrusion are determined by hydraulic gradients and hydraulic conductiv-
93 ity (Stewart, 1999), so in coastal gravel barrier environments where tidal water level fluctuations may lead
94 to highly dynamic and even reversing hydraulic gradients and where $K \approx 1000$ m day⁻¹, saline intrusion
95 is potentially of great importance. With few exceptions (Erskine, 1991; Austin and Masselink, 2006b; Mao
96 et al., 2006; Turner and Masselink, 2012), the vast majority of research on coastal aquifer dynamics has been
97 conducted along sandy shores with typical values for the hydraulic conductivity K $O(0.0001$ m s⁻¹ or 10 m
98 day⁻¹). Gravel is much more permeable than sand, with K $O(0.01$ m s⁻¹ or 1000 m day⁻¹), and a coastal
99 aquifer along a gravel shore is therefore expected to be significantly more responsive to oceanic water table
100 fluctuations (waves, tides, storm surges).

101 The aim of this paper is to describe and discuss coastal aquifer dynamics across two macro-tidal gravel
102 barrier systems backed by fresh water lagoons. Groundwater level and conductivity measurements were
103 used to determine the necessary properties of the coastal aquifer required to address the potential for
104 saline intrusion. It will be demonstrated that although salt water penetrates into the gravel barriers for a
105 considerable distance, the width of the barrier systems and the relatively high water level of the fresh water
106 lagoons inhibit saline intrusion into the freshwater lagoons.

107 2. Field methods

108 2.1. Field sites

109 Groundwater, tidal and lagoon levels were monitored during 2009–2011 at Slapton Sands, Devon, and
110 during a two-week period in 2012 at Loe Bar, Cornwall, UK (Fig. 2).

111 *2.1.1. Slapton Sands*

112 Slapton Sands is a 4-km long gravel barrier with a width of 100–140 m and a crest elevation of 6–7 m above
113 Ordnance Datum Newlyn (ODN; Fig. 3). The barrier is aligned with a roughly north–south orientation
114 and is backed by a shallow freshwater lagoon (Slapton Ley). The lagoonal water level is approximately 1
115 m higher than the spring high tide level. The beach has a mean intertidal gradient of $\tan\beta = 0.15$ and a
116 median sediment size D_{50} of 6 mm (Austin and Masselink, 2006a). The beach faces east into the English
117 Channel and is consequently sheltered from Atlantic swell. The local wave climate is dominated by periods
118 of southerly and easterly wind-waves. The tidal regime is macro-tidal with spring and neap ranges of 4.3
119 and 1.8 m, respectively.

120 *2.1.2. Loe Bar*

121 Loe Bar is a 1-km long fine-gravel barrier with a maximum width of 250 m and a crest elevation of 9
122 m ODN (Fig. 3). Loe Bar is aligned roughly east-west and is backed by Loe Pool, a shallow freshwater
123 lagoon. The lagoonal water level is approximately 1.5 m above spring high tide level. The beach has a mean
124 intertidal gradient of $\tan\beta = 0.11$ and a median sediment size measured from sediment cores of D_{50} of 2
125 mm. The beach faces south-west into the English Channel and receives energetic Atlantic swell. The tidal
126 regime is macro-tidal with mean spring and neap ranges of 4.7 and 2.2 m, respectively.

127 *2.1.3. Water-level control*

128 The lagoon water levels at both Slapton Sands and Loe Bar are artificially controlled by drainage weirs,
129 which are active during high water levels in order to minimise localised flooding events. At Slapton, van
130 Vlymen (1979) described the lagoon as flow dominated, with a small storage capacity and an unstable water
131 level, which responds rapidly to increased inflow. Therefore through-barrier drainage is not the principal
132 factor in controlling lagoon levels.

133 *2.2. Boreholes*

134 At Slapton, five groundwater monitoring boreholes were installed into the barrier by rotary drilling
135 during September 2009. The boreholes penetrate to a depth of approximately -2 m ODN. Each borehole
136 contains a 63 mm diameter polyurethane groundwater well, machine slotted from 0.5 m below ground level
137 to the base. The slotted section of each well is covered by a 250 μm geotextile sock to prevent the ingress of
138 fine sediments. The upper sections of the boreholes are capped with bentonite clay to prevent the vertical
139 ingress of surface water run-off and are topped with a locking steel cover. Similar wells were installed at Loe
140 Bar during March 2012, but these only penetrate to approximately MSL. It is worth noting that, in relation
141 to the size of the barrier, the spatial coverage of the wells at Loe was less than at Slapton Sands.

142 *2.3. Groundwater monitoring*

143 *2.3.1. Slapton*

144 Each groundwater well was equipped with a self-logging LevelTroll absolute pressure transducer, con-
145 tinuously recording pressure and temperature at one-minute intervals; a similar sensor recorded the level of
146 Slapton Ley. A gauge installed on the headland (Matthew’s Point) between Slapton and Blackpool Sands
147 sampled the tidal elevation. Barometric pressure was recorded by an additional sensor located in the top-
148 cover of one of the wells; this was reduced to sea-level and used to correct the LevelTrolls for variations in
149 atmospheric pressure. The positions of all sensors were surveyed using an electronic total station and the
150 sensor elevations reduced to ODN. The borehole pressure transducers were downloaded every three months
151 and the tide gauge bi-annually.

152 A self-recording micro CTD (conductivity, temperature and depth) sensor (INW CT2X) was variously
153 installed into wells BH3–BH5 for periods ranging from 4 to 7 weeks. The CTD was used to measure the
154 groundwater conductivity from which to infer the propagation of salt water into the barrier.

155 2.3.2. Loe Bar

156 At Low Bar, each groundwater well was equipped with a self-logging RBR TWR2050 absolute pressure
157 transducer, which recorded pressure and temperature at one-minute intervals. As at Slapton, further sensors
158 were installed into Loe Pool and Porthleven harbour (2-km to the north-west of the field site) to record
159 the lagoon and tidal water levels, respectively. Two INW CT2X CTD sensors were deployed at Loe Bar to
160 measure groundwater conductivity. BH2 was monitored throughout the field experiment, while BH1 and
161 BH3 were each monitored by the CTD sensor for separate 1-week periods.

162 3. Results

163 3.1. Water levels

164 To illustrate the range of water levels observed within the groundwater, lagoon and ocean at Slapton, Fig.
165 4 plots one year of data recorded by the borehole pressure transducers, tide gauge and wave buoy. Water
166 level variations at four temporal scales can be clearly identified in the groundwater data: (1) a seasonal-scale
167 variation with elevated water levels during winter months; (2) tidal variation at spring-neap and (3) semi-
168 diurnal frequencies; and (4) storm-event scale variations linked to large wave events. The lagoon elevation
169 remains approximately 1 m above the spring high tide elevation and variations in the lagoon water level
170 appear to be at the seasonal and storm-event scales only.

171 The energy spectrum of the ocean water level fluctuations at Slapton was computed from the average
172 of 16 detrended (to remove seasonal fluctuations) 29-day segments with 50% overlap. The spectrum clearly
173 identified the key tidal constituents and demonstrated the dominance of the semi-diurnal tide (M2,S2) with
174 a period (t_0) of 12.4 hours and the spring-neap variation (14.5 days).

175 The two-week deployment at Loe Bar reveals groundwater oscillations at the semi-diurnal, spring neap
176 and storm-event timescales; the lagoon level is steady over these timescales (Fig. 5). The lagoon level at Loe
177 Bar is approximately 1 m higher than Slapton Ley and the mean groundwater elevation within the barrier
178 is ~ 0.5 m greater. Similarly to Slapton, the Lagoon elevation remains above the spring high tide elevation,
179 in this case by 1.5–2 m.

180 3.2. Aquifer properties

181 3.2.1. Slapton

182 The tidal damping method, Equations (2) and (4), was used to determine TE and t_L for each of the
183 boreholes over 12.4 hour periods resulting in >700 temporal observations. TE was computed as the ratio
184 of the the standard deviation of the water level in the borehole to the standard deviation of the ocean tide
185 level, thereby using all of the data rather than just peak amplitude readings (Erskine, 1991). The temporal
186 lag t_L was computed from the cross-correlation of the water level in each borehole with the ocean tide
187 elevation, and defined as the temporal lag corresponding to the strongest positive cross-correlation peak.
188 The cross-shore distance x for each borehole, was defined as the mean distance from each borehole to the
189 intersection of the ocean tidal elevation with the beach profile for that 12.4 hour period.

190 The relationship between tidal damping and distance from the shoreline is plotted in Fig. 6. Five large
191 point clouds of TE , each relating to an observation well, display a very weak decay moving landwards away
192 from the shoreline ($x = 0$). The best-fit exponential curve was fitted through the data and suggests that
193 the effect of the ocean tidal variation should be observed at least to the seaward shoreline of the freshwater
194 Ley at $x = 120$ m. Similar point clouds for t_L display a linear increase moving landwards away from the
195 shoreline as suggested by Equation (1) and by e.g. Erskine (1991); Turner et al. (1997).

196 The slopes of the regression analysis provide the damping coefficient ($\beta = -0.0193 \text{ m}^{-1}$) and slope ($a =$
197 1.534 min m^{-1}). Utilising Equations (3) and (5) with $t_0 = 12.41$ hours and $S = 0.25$ (standard value for
198 medium gravel; e.g. Morris and Johnson (1967); Heath (1983)), T is calculated as: $T = 0.4047 \times 10^4 \text{ m}^2 \text{ d}^{-1}$
199 (TE); $T = 0.906 \times 10^4 \text{ m}^2 \text{ d}^{-1}$ (t_L).

200 Hydraulic conductivity K was calculated using Equation (6), where the mean value for b was determined
201 as 5.6 m from the depth of the clay horizon (-5 m ODN) observed during the borehole drilling and through
202 electrical resistivity measurements at Slapton (Massey et al., 2006). K is estimated as: $K = 0.0084 \text{ m s}^{-1}$

203 (TE); $K = 0.019 \text{ m s}^{-1}$ (t_L). It is encouraging that K determined using both the TE and t_L methods is
 204 almost the same order of magnitude, with K_{t_L} approximately twice K_{TE} .

205 3.2.2. Loe Bar

206 At Loe Bar, the tidal damping method as employed at Slapton was used over 12.4 hour periods throughout
 207 the deployment to provide 24 estimates of TE and t_L . The results are plotted in Fig. 7 and the exponential
 208 and linear relationships are fitted to the data; however, the exponential relationship for TE is again very
 209 weak.

210 From the slopes of the regression analysis the damping coefficient is $\beta = -0.0128 \text{ m}^{-1}$ and slope $a = 0.931$
 211 min m^{-1} (Fig. 7). Using the same values for t_0 and S as for Slapton, T is estimated as: $T = 0.9293 \times 10^4$
 212 $\text{m}^2 \text{ d}^{-1}$ (TE); $T = 2.456 \times 10^4 \text{ m}^2 \text{ d}^{-1}$ (t_L). K was calculated using Eq. 6 as $K = 0.013 \text{ m s}^{-1}$ (TE); $K =$
 213 0.035 m s^{-1} (t_L), assuming a mean saturated aquifer thickness b of 8 m, determined from the cross-barrier
 214 groundwater profiles and borehole sediment cores. Table 1 summarises the measured and inferred aquifer
 215 properties for Slapton Sands and Loe Bar. The parameters computed at both sites are very similar with T
 216 and K being of the same order of magnitude, $O(10^4) \text{ m}^2 \text{ d}^{-1}$ and $O(10^{-2}) \text{ m s}^{-1}$, respectively.

217 **TABLE 1**

218 3.3. Hydraulic gradients

219 The rise and fall of the ocean water level at the beachface forces similar variations within the groundwater
 220 and establishes time-varying horizontal hydraulic gradients dh/dx (Fig. 8). During spring tides, with typical
 221 ranges >4 m, the amplitude of the groundwater variations through the boreholes is ~ 1.5 m, whereas during
 222 neap tides, when the tide range is ~ 2 m, the groundwater amplitude variations are ~ 0.5 m; this is roughly
 223 in agreement with the predicted linear scaling between tidal and groundwater amplitude in Equation (1).
 224 Significant phase lags and amplitude attenuation, which increase in the landward direction, are evident in
 225 the groundwater oscillations when compared to the ocean tidal signal and are indicative of tidal damping
 226 through the aquifer. Consistent with previous observations (e.g. Emery and Foster, 1948), the groundwater
 227 oscillations are also skewed, displaying a faster rise during the flood tide and slower decay during the ebb.

228 To estimate the local hydraulic gradient, a 2-point method was used, whereby the measured head between
 229 adjacent pairs of sensors was differenced and normalised by the cross-shore separation between the pairs.

230 For the spring tide case (Fig. 8), the ocean tidal elevation begins to exceed the elevation of the ground-
 231 water in the boreholes during the mid-flood and a negative dh/dx (landwards-directed) is rapidly established
 232 and propagates landwards. $-dh/dx$ is maximum just before high tide ($dh/dx = -0.05$), before beginning to
 233 reduce approximately 2-hours after high water as the ocean tidal elevation decreases and the groundwater el-
 234 evation increases due to the lagged landward flux of groundwater. The maximum positive (seaward-directed)
 235 dh/dx is established around low tide ($dh/dx = 0.04$), as the falling groundwater levels coincide with the
 236 minimum ocean tidal elevation. Across the back-barrier region, dh/dx remains approximately zero or just
 237 positive. The negative (landwards-directed) dh/dx during the neap tide case are approximately 30% of those
 238 observed for the spring tide and the rate of change over time is also significantly slower; their phasing with
 239 respect to the ocean tide is similar.

240 At Loe Bar, the horizontal hydraulic gradients follow the same trends as at Slapton, but are significantly
 241 smaller (Fig. 9). During spring tide conditions, the maximum offshore-directed gradient is $dh/dx = 0.02$, 50
 242 % of that observed at Slapton; the maximum onshore-directed gradient is 20 % of that at Slapton ($-dh/dx =$
 243 0.01). During neap tides, the offshore-directed gradient is $dh/dx = 0.01$ and the onshore-directed gradients
 244 are negligible.

245 3.4. Barrier discharge

246 The flow of groundwater through a porous media can be expressed through Darcy's Law (Darcy, 1856)
 247 and is given by:

$$248 \quad Q = -KA \frac{dh}{dx} \quad (7)$$

249 where Q is the volume of water that flows through cross-section A per unit time, under the local hydraulic
 gradient dh/dx . The constant of proportionality K is the hydraulic conductivity. Estimating K as 0.01, the

250 Reynolds number is <10 , so Slapton and Loe Bar remain within the acceptable limits for assuming Dacian
251 flow.

252 The cross-barrier discharge at Slapton was determined by summing Q computed between each pair of
253 wells (excluding the Ley sensor) with equation (7) and then averaging over consecutive 24-hour periods (Fig.
254 10a). The mean daily discharge was computed as $1.5 \times 10^3 \text{ m}^3 \text{ day}^{-1}$, per unit barrier width. Comparison
255 with Figure 4 reveals no apparent correlation between Q and the tidal elevation, whereas the large discharge
256 peaks in e.g. November, January and March appear to correlate with peaks in the Ley elevation (h_{Ley}) and
257 H_{rms} . To confirm this observation, the daily time series of Q were cross-correlated against h_{Ley} , H_{rms} and
258 the daily tide range.

259 Q is strongly positively correlated with h_{Ley} ($r = 0.72$) with a time lag of zero, indicating that peaks in
260 the Ley elevation and discharge are coincident. Q is also positively correlated with H_{rms} ($r = 0.5$) at a time
261 lag of -1-day, suggesting that Q peaks 1 day after large wave events. The smaller value of the correlation
262 coefficient r suggests that the relationship with H_{rms} is weaker than with h_{Ley} . The correlation with the
263 ocean tide range is very low, and hence possibly not significant, but it suggests that daily discharge is
264 negatively correlated with ocean tidal range with greater net discharge occurring 4–5 days after spring tides.

265 The discharge results for Loe Bar (not shown) are smaller than those measured at Slapton, with a mean
266 discharge of $1.2 \times 10^3 \text{ m}^3 \text{ day}^{-1}$ per unit barrier width. The short length of the time series precludes any
267 meaningful correlation analysis, but the mean discharge is probably representative.

268 3.5. Aquifer conductivity

269 At Slapton, groundwater conductivity measurements were made in the three seaward-most boreholes and
270 act as a proxy for salinity (Fig. 11; Table 2). The specific conductivity of the ocean water was measured as
271 $4.23 \times 10^5 \mu\text{S cm}^{-1}$ and the mean groundwater conductivity decreased rapidly moving landwards towards
272 the Ley, where the specific conductivity was $250 \mu\text{S cm}^{-1}$. Two conductivity probe deployments in BH5,
273 for a total of 80 days, show a mean conductivity of $15493 \mu\text{S cm}^{-1}$ and indicate significant variation with
274 ocean tidal elevation at both the semi-diurnal and spring-neap timescales ($\sigma_C = 9678 \mu\text{S cm}^{-1}$). There is
275 also some indication of variation due to wave forcing (i.e. Jun 2011), where the conductivity variance is
276 increased during neap tide periods. BH4 displays similar amplitude variations in conductivity to BH5, but
277 the mean conductivity is $\sim 40\%$ lower ($9537 \mu\text{S cm}^{-1}$). Conductivity measured within BH3 is very close
278 to that of the Ley, near-constant ($292 \mu\text{S cm}^{-1}$) and does not display any significant variation at tidal
279 frequencies ($\sigma_C = 53 \mu\text{S cm}^{-1}$); several small oscillations during late December are probably due to wave
280 forcing. A very short deployment spanning several tidal cycles with the CTD deployed in BH2 (not shown)
281 did not indicate any variation in conductivity.

282 [TABLE 2]

283 At Loe Bar, groundwater conductivity was very low and relatively constant over the present temporal
284 and spatial scales (Fig. 12; Table 2). The landward-most well BH1 has a constant conductivity of $291 \mu\text{S}$
285 cm^{-1} ($\sigma_C = 11 \mu\text{S cm}^{-1}$), without the semi-diurnal variations in conductivity observed at Slapton. BH2
286 and BH3, located further seawards, display slightly elevated conductivity ($383\text{--}462 \mu\text{S cm}^{-1}$), but with
287 minimal temporal variation and hence small standard deviations ($47\text{--}70 \mu\text{S cm}^{-1}$). The elevated water
288 levels recorded in BH2–3 towards the end of the deployment period do not lead to increased conductivity.
289 Overall, the conductivity results for Loe Bar suggest that seawater does not significantly propagate into the
290 barrier to the location of the bore holes.

291 3.6. Lagoon-groundwater shoreline decoupling

292 At the ocean shoreline the groundwater level is (approximately) coupled to the ocean water level as shown
293 by Equation (1). However, observations made on the back-barrier region at both field sites indicate that this
294 is not the case at the lagoon shoreline. Fig. 13a-b plot the envelopes of groundwater and lagoon water levels
295 and highlight that the groundwater level remains significantly lower than the lagoon level; extrapolating the
296 mean water surface between these points results in unrealistically large hydraulic gradients.

297 In the region close to the edge of the lagoon, where no boreholes were present, observation pits were
298 excavated to determine the depth of the water table (Fig. 13c). At Loe Bar, this pit was excavated to a

299 depth of 1.9 m before reaching the groundwater, confirming that the barrier water table does not intersect
300 with the lagoon shoreline and is therefore decoupled from the edge of the lagoon. A horizontal tunnel dug
301 from the excavation pit and extending underneath the lagoon bed encountered non-saturated sediments,
302 further confirming that the lagoon level does not represent the terrestrial water table and is in fact perched.
303 The observations at Slapton were similar.

304 Observations suggest that the bottom of the lagoon is impermeable in the region adjacent to the shoreline
305 and that there is no vertical infiltration of water from the lagoon to the groundwater. Sedimentological
306 analysis indicated that there was no significant difference in grain size distribution between the lagoon
307 bed and barrier matrix. This therefore leaves the question of how the lagoon and barrier groundwater are
308 actually coupled, since Fig. 10 indicates that changes in the lagoon water level are reflected in the barrier
309 groundwater with zero time lag.

310 4. Discussion

311 Detailed field measurements of groundwater levels and oceanic forcing conditions collected at two coastal
312 gravel barriers backed by freshwater lagoons within the UK show that the cross-barrier hydraulic gradients
313 are highly dynamic at ocean tide and wave-event timescales. Saline water penetrates a considerable distance
314 landwards, but net seaward-directed hydraulic gradients and high lagoon elevations prevent saline intrusion
315 into the lagoons. In the context of the subterranean estuary (e.g. [Robinson et al., 2007](#)), we observe an upper
316 saline plume driven by tide- and wave-induced circulation and a lower lagoon-driven freshwater discharge.
317 It is also observed that the groundwater table is decoupled from the lagoon shoreline, which may have
318 significant implications for the numerical modelling of such environments.

319 Barrier groundwater levels at both field sites were observed to fluctuate principally at the semi-diurnal
320 tidal frequency with a period of 12.4 hours. Consistent with previous studies on sandy and gravel beaches
321 ([Turner et al., 1997](#); [Turner and Masselink, 2012](#)), large wave events also resulted in a super-elevation of the
322 water table across the barrier. The lagoonal water levels remained elevated 1 m and 2 m above the MHWS
323 elevation at Slapton and Loe Bar, respectively. These observations indicate that there must be seaward
324 discharge because there is a substantive hydraulic gradient across the barrier, modulated by the oceanic
325 forcing. To determine the net discharge a Darcian approach was followed whereby the aquifer properties
326 and hydraulic gradients were quantified.

327 The aquifer properties including the hydraulic conductivity K were computed at Slapton and Loe Bar
328 using the tidal damping method giving $K = O(0.01) \text{ m s}^{-1}$. The results were consistent between the two
329 sites using both the tidal efficiency and time lag methods and are comparable to the few previous large
330 scale observations of K . The present estimates are approximately an order of magnitude lower than that
331 obtained by [Turner and Masselink \(2012\)](#) in a prototype-scale laboratory experiment with well-sorted coarse
332 gravel ($D_{50} = 11 \text{ mm}$) of $K = 0.16 \text{ m s}^{-1}$. This is consistent with the significantly finer, more poorly sorted
333 gravel and increased proportion of fines in the present field case. It is noteworthy that these values of K are
334 one–two orders of magnitude greater than those along sandy shores where the majority of previous research
335 into coastal aquifer dynamics has occurred.

336 A common trend throughout both the Slapton and Loe Bar data is the very weak decay in the amplitude
337 of the landwards-propagating ocean tidal signal past the barrier crest. Figures 6 and 7 indicate that there is a
338 significant decay of approximately 60% between the shoreline and the seaward-most borehole, but landwards
339 of that point there is almost no further attenuation of the amplitude signal; however, there is a significant
340 time lag that increases moving landwards. It is thought that this behaviour is due to a departure from one
341 of the simplifying assumptions of the one-dimensional groundwater model: a confined aquifer with a flat
342 base.

343 The present unconfined aquifer allows variations in transmissivity, which result from fluctuations in the
344 phreatic surface ([Erskine, 1991](#)). Combining this with the suggestion from the present data and previous
345 surveys (e.g. [Massey et al., 2006](#)) that the aquifer base at Slapton probably slopes upwards moving landwards
346 (due to barrier roll-over), becoming thinner towards the lagoon, it is likely that the groundwater wave shoals
347 moving landwards, minimising the amplitude decay but retaining the phase lag. It is unfortunate that we

348 do not have boreholes located in the rapidly decaying section of the theoretical curves between 0 and 50 m
349 and 0 and 120 m from the shoreline at Slapton and Loe, respectively, which would increase our confidence
350 in the results. However the difficulty of installing wells in such locations is that they would be on the
351 exposed gravel beachface open to wave attack and run-up immersion. Due the above observations, it is
352 preferable to use the time-lag derived aquifer properties; however, the values derived using both the time-lag
353 and tidal-efficiency are very similar.

354 The measured hydraulic gradients across both barriers are highly dynamic and are principally modulated
355 at the semi-diurnal tidal frequency. Maximum landward-directed gradients of -0.05 (during spring tides at
356 Slapton) are observed across the seaward face of the barrier around high tide as the ocean water level rises
357 across the beachface and these propagate 50 m landwards. The maximum seaward-directed gradients of 0.04
358 occur at low tide and result from the superposition of oceanic water draining from the beach and the net
359 seepage of terrestrial groundwater/lagoon water. During neap tides, the phasing of the hydraulic gradients
360 is similar, but their magnitude is reduced by approximately 70 % and they only penetrate 40 m landwards.
361 At Loe Bar the net hydraulic gradients are also seaward directed and follow the same trends as at Slapton,
362 but are smaller due to the increased barrier width.

363 Daily mean values of the net barrier discharge at both Slapton and Loe Bar were always positive and
364 hence seaward-directed. For Slapton, assuming that the barrier is alongshore uniform and homogenous with
365 a wetted gravel length of 3.57 km, multiplying the discharge per unit width by the barrier length provides a
366 mean barrier through flow of $5.4 \times 10^6 \text{ m}^3 \text{ day}^{-1}$. This is the same order of magnitude as the daily seepage
367 discharge estimated via water balance by [van Vlymen \(1979\)](#). At Loe Bar the daily discharge is $4 \times 10^5 \text{ m}^3$
368 day^{-1} for a wetted barrier length of 0.32 km.

369 The net barrier discharge is principally due to the lagoon-driven discharge as indicated by the strong
370 correlation between lagoon-level and daily discharge. During spring tides there is a decrease in net discharge,
371 although the head differences between the groundwater and ocean are maximised, and the hydraulic gradients
372 are large. This is somewhat contrary to the increased discharge observed shortly after large wave events. It
373 is suggested that the ocean tide-induced landward-directed flux during spring tides strongly interacts with
374 the opposing net seaward-directed lagoon discharge, thus reducing the discharge compared to that observed
375 during smaller tide ranges when the landward-directed oceanic flux is smaller. This is demonstrated in
376 Fig. 8, where an increased hydraulic gradient is observed around high tide at the back-barrier indicating a
377 mounding of water at the edge of the lagoon as the inflowing tidal waters hold-up the out-flowing freshwater.

378 The wave-induced circulation is expected to be conceptually similar to that of the ocean tide, but with
379 significantly smaller volumes of water and at a shallower depth in the aquifer ([Cooper Jr, 1959](#); [Robinson
380 et al., 2007](#)). However, unlike for the ocean tidal case, we observe a strong positive correlation between
381 wave events and barrier discharge with a 1-day lag. This is probably due to the wave events blocking up the
382 outflow drain from Slapton Ley. The drain is the principal outflow route from the lagoon weir (e.g. [Burt
383 and Heathwaite, 1996](#)) and it flows from a narrow tunnel across the beach at the southern, Torcross, end of
384 the barrier; it is hence vulnerable to being effected by wave-driven morphological change on the beachface.
385 The blockage of the drain is subsequently followed by a rapid increase in the water level of the lagoon, which
386 is observed in Fig. 4 and thus an increase in the net seaward-directed hydraulic gradient and discharge.

387 Conductivity measurements within the boreholes indicate that there is very limited potential for saline
388 intrusion into the lagoons at Slapton or Loe Bar via the groundwater pathway. At Slapton, significant semi-
389 diurnal variation was observed in the two seaward-most bore holes (BH4-5), but the maximum conductivity
390 measured at BH5 was an order of magnitude less than the seawater and the mean value 2 orders less.
391 The conductivity reduced rapidly moving landwards and by BH3 was consistent with the Ley waters and
392 displayed no semi-diurnal and very minimal wave-induced variability. The measured conductivity across all
393 bore holes at Loe Bar was very low with little spatial or temporal variability. Overall the measured limit of
394 saline intrusion from the mean shoreline at Slapton was 86 m (BH3). At Loe Bar, the landward boundary
395 was a maximum of 129 m (BH3) from the shoreline.

396 It was observed at both field sites that at the lagoon edge the water table was around 2 m below the ground
397 surface and thus the shoreline of the lagoons were decoupled from the groundwater table. Clearly the lagoons
398 and the groundwater are coupled, since it has been shown that the elevation of the lagoons are of first-order
399 importance in driving subterranean groundwater discharge through the barrier, but this finding suggests

400 that they are coupled at some depth and it is seepage through the base of the lagoon that is important.
401 This is different from observations made in two recent prototype-scale laboratory experiments (BARDEX;
402 Turner and Masselink (2012) and BARDEX II; Masselink et al. (submitted)), where the sediments were
403 well-sorted and the lagoon shoreline remained coupled to the water table. This observation highlights the
404 probable role of fine particles and biological matter that has settled-out across the shallow lagoon periphery
405 and formed a very thin impermeable layer. It also raises an important question for modelling such coastal
406 systems, e.g., how should the barrier-lagoon boundary be treated?

407 For the numerical modelling of barrier groundwater-ocean dynamics it is clearly insufficient to extrapolate
408 the groundwater table as a continuum between the lagoon and ocean shorelines (e.g. Williams et al., 2012),
409 which will significantly over-estimate the hydraulic gradients across the back-barrier. A simple alternative
410 would be to retain the fixed head assumption, but rather than the fixed head being at the elevation of the
411 lagoon, it should correspond to the expected seepage depth from the lagoon base.

412 5. Conclusions

413 Field monitoring campaigns were carried out on two macro-tidal coastal gravel barriers backed by fresh-
414 water lagoons to investigate the groundwater dynamics and the potential for saline intrusion. Groundwater
415 and lagoon elevation and conductivity, and oceanic tide and wave forcing were monitored using pressure
416 transducer-logged boreholes and gauges for 1-year at Slapton Sands and 2-weeks at Loe Bar, respectively.
417 It is concluded that:

- 418 1. The groundwater levels are highly dynamic across the entire width of the barriers, fluctuating at the
419 semi-diurnal ocean tidal frequency with a period of 12.4 hours. Large ocean wave events during storms
420 result in a super-elevation of the groundwater across the barriers.
- 421 2. The ocean tidal signal becomes increasingly lagged and attenuated as it propagates landwards across
422 the barriers. These properties are used to determine the hydraulic conductivity K of the barriers via
423 the one-dimensional unsteady groundwater flow model. K is $O(0.01)$ m s⁻¹ at both the Slapton and
424 Loe Bar field sites.
- 425 3. The net barrier discharge is principally controlled by the elevation of the lagoons. The lagoons were
426 elevated 1–2 m above the MHWS elevation, thus establishing a seaward-directed hydraulic gradient
427 and hence discharge. At Slapton and Loe Bar the mean daily discharge was 1.5×10^3 and 1.2×10^3
428 m³ day⁻¹ per unit barrier width, respectively.
- 429 4. Barrier discharge peaks around 4 days after the highest spring tides. It is hypothesised that during
430 the peak spring tides, the strong landwards-directed hydraulic gradients reduce the net seaward flux
431 of freshwater. Discharge is also strongly positively correlated to large wave events, but with a lag of
432 1-day. It is suggested this is due to the blockage of the outflow weir drain from the lagoon, which flows
433 across the beachface, with gravel.
- 434 5. The shoreline of the lagoon was observed to be decoupled from the groundwater table at both field
435 sites. The groundwater elevation was 1–2 m lower, suggesting that seepage from the lagoon to barrier
436 groundwater system occurs through the base of the lagoon. This is of potential significance to the
437 modelling of coastal gravel barriers, since extrapolating the groundwater table to the edge of the lagoon
438 will produce unrealistically large hydraulic gradients.
- 439 6. The potential for saline intrusion into the freshwater lagoons is low. Groundwater conductivity mea-
440 surements demonstrated that although salt water penetrates some distance landwards into the barriers
441 (c. 60 m from spring high tide level), the width of the barrier systems (120 and 275 m) and the rela-
442 tively high water level of the fresh water lagoons (c. 0.75–2 m above spring tide level) inhibit saline
443 intrusion.

444 Acknowledgements

445 This project was funded by a Seale-Hayne Educational Trust Grant awarded to MA and GM and an
446 Environmental and Physical Sciences Research Council grant (EP/H040056/1) awarded to GM. We would

447 like to thank the Field Studies Council and the Whitley Wildlife Trust for their assistance at Slapton Sands,
448 and the National Trust for their support at Loe Bar. Tim Scott and Pedro Melo de Almeida are thanked
449 for their field assistance.

(Top) Tidal water level (grey line) and groundwater elevation at each of the five boreholes. (Bottom) Contours of hydraulic gradient dh/dx (positive seawards), where the solid black markers indicate the cross-shore location of the boreholes and the thick black line the movement of the ocean shoreline.

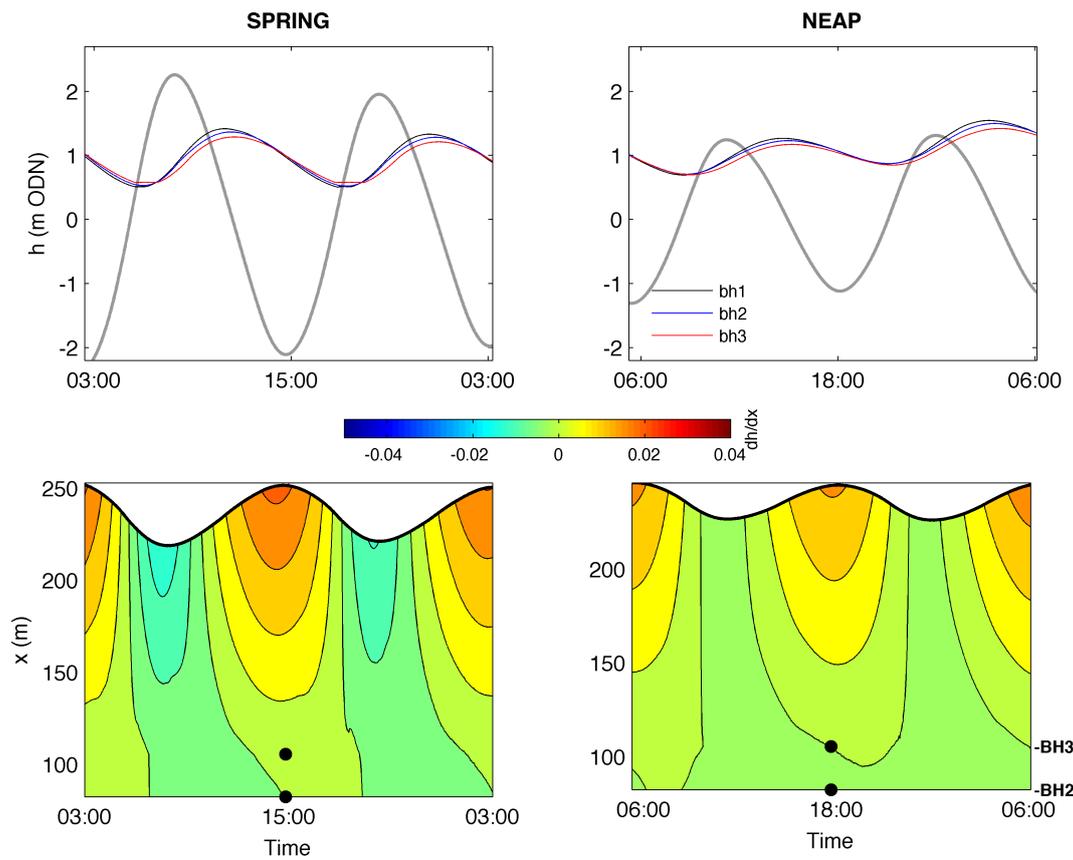

Figure 9: Groundwater level variations and hydraulic gradients at Loe Bar during the spring (left) and neap (right) tides highlighted in Fig. 5. (Top) Tidal water level (grey line) and groundwater elevation at each of the five boreholes. (Bottom) Contours of hydraulic gradient dh/dx (positive seawards).

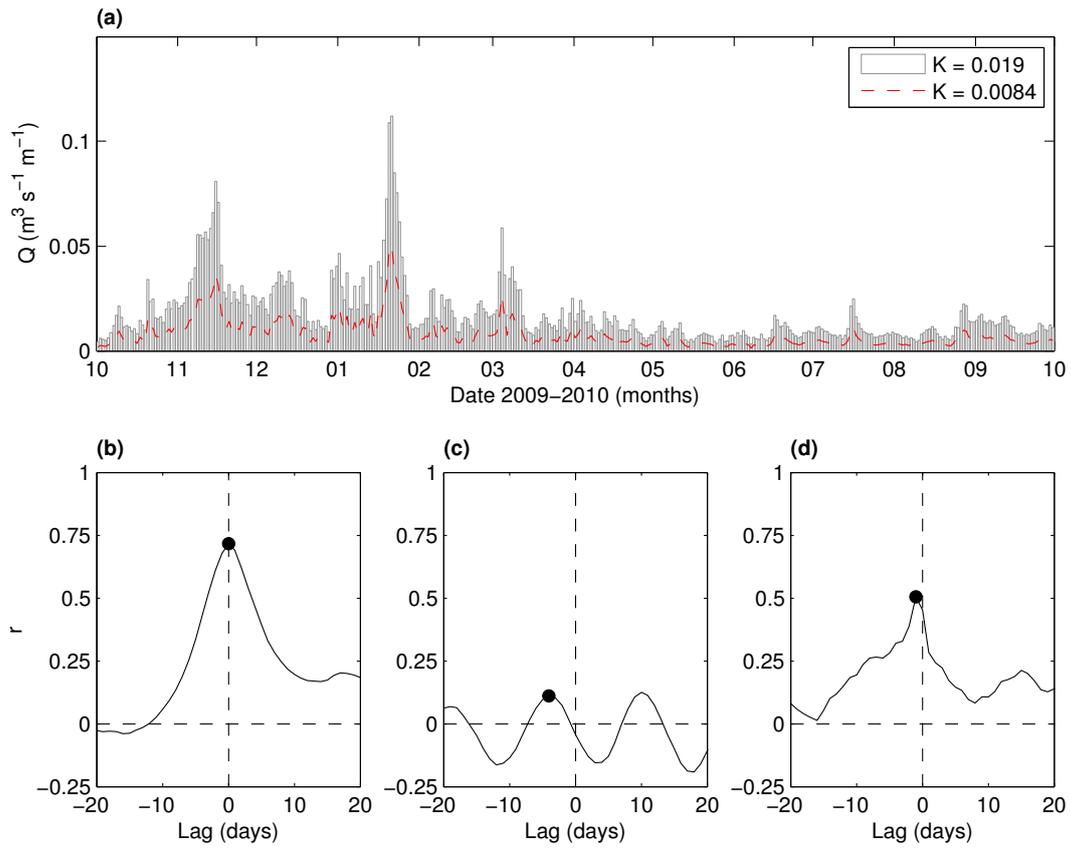

Figure 10: Slapton groundwater discharge Q . (a) Daily-averaged groundwater discharge per unit barrier width for the two computed values of K , positive seawards; cross-correlation of daily-averages of (b) Q and the Ley elevation; (c) Q and the tidal range; and (d) Q and H_{rms} . Solid dots indicate the time lag at the maximum positive correlation.

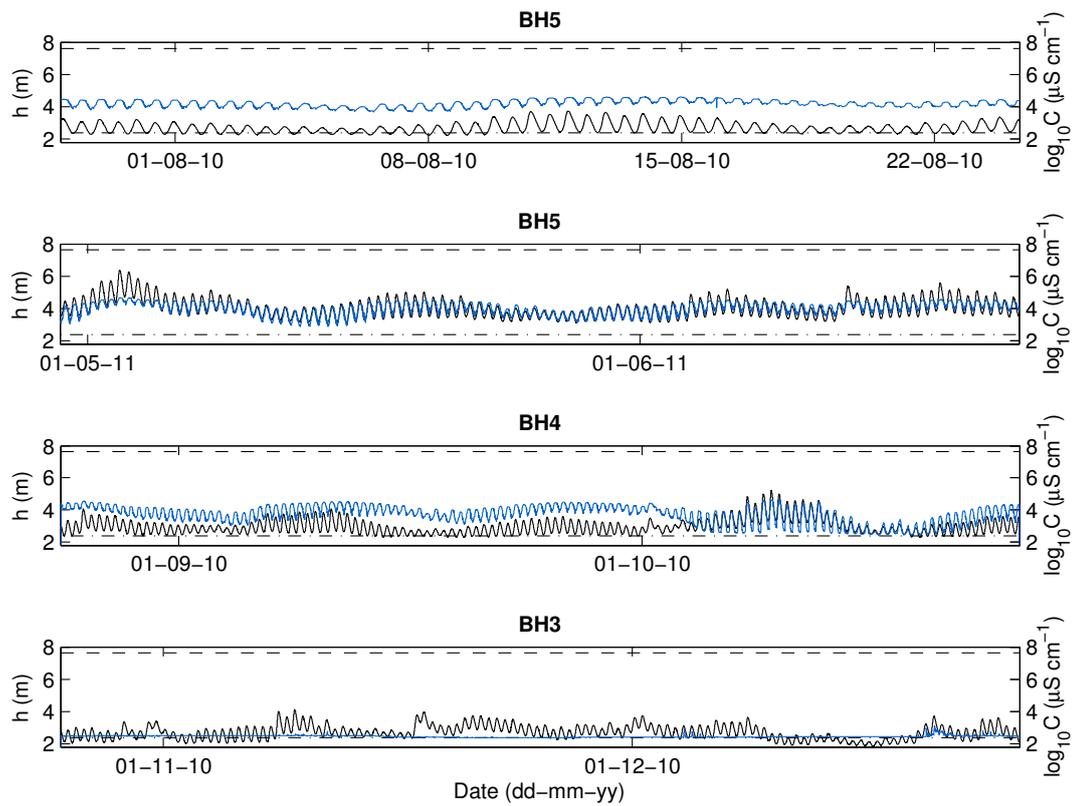

Figure 11: Time series of groundwater conductivity (blue lines, right axis, log-scale) and groundwater level (black lines, left axis) measured in boreholes BH3–BH5. The horizontal dashed black line indicates the measured log-scale seawater conductivity and the dot-dash line the Ley conductivity. Note that the time periods are not coincident.

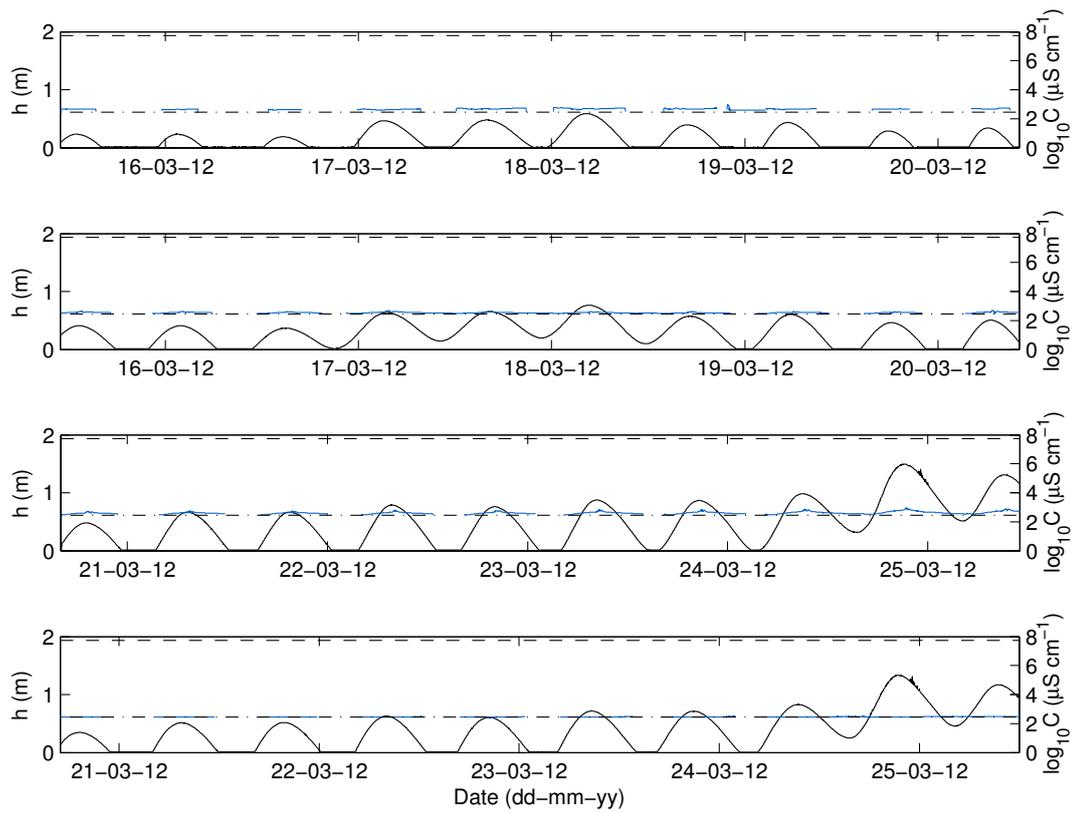

Figure 12: Time series of groundwater conductivity (blue lines, right axis, log-scale) and groundwater level (black lines, left axis) measured in boreholes BH1–BH3. The horizontal dashed black line indicates the measured log-scale seawater conductivity and the dot-dash line the lagoon conductivity. Note that the time periods for panels 1 and 2, and 3 and 4, respectively, are coincident. The gaps in the conductivity record are due to the sensor drying out.

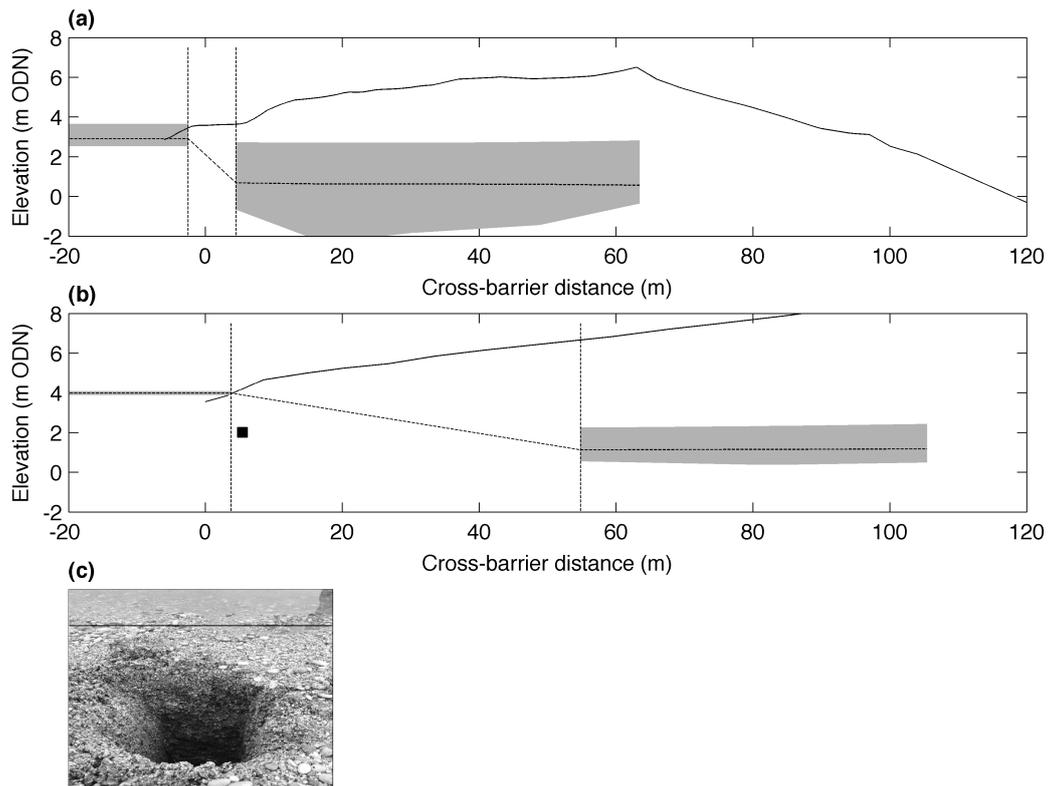

Figure 13: Lagoon-groundwater decoupling. Cross-barrier profiles indicating the envelope of groundwater and lagoon water levels (grey shading) for (a) Slapton and (b) Loe Bar. The vertical dashed lines indicate the region at the lagoon edge with no direct groundwater level measurements. The horizontal dashed lines show the mean groundwater profile (inferred between the vertical dashes). (c) Photograph of the observation pit excavated close to the lagoon at Loe Bar. The solid line highlights the lagoon shoreline. The solid square in (b) plots the location of the base of the observation pit.

Table 1: Summary of the aquifer properties inferred from measurements at Slapton Sands and Low Bar. TE is the tidal efficiency method and t_L is the tidal lag method.

	Slapton Sands		Loe Bar	
	TE	t_L	TE	t_L
a (min m ⁻¹)	-	1.5344	-	0.931
β (m ⁻¹)	-0.0193	-	-0.0128	
T (m ² d ⁻¹)	0.4047×10^4	0.906×10^4	0.9293×10^4	2.456×10^4
S (-)	0.25	0.25	0.25	0.25
b (m)	5.6	5.6	8	8
K (m s ⁻¹)	0.0084	0.019	0.013	0.035

Table 2: Overview of measured groundwater conductivity in the boreholes. x is the distance landwards from the mean shoreline position. Note: measured seawater conductivity at Slapton = $4.23 \times 10^5 \mu S \text{ cm}^{-1}$.

	\bar{C}	σ_C	min(C)	max(C)	x
	($\mu S \text{ cm}^{-1}$)	(m)			
Slapton
