Contents

39 **Abbreviations and definitions**

Term	Abbreviation	Definition
Above ordnance datum	AOD	Height (in m) above mean sea level at Newlyn
Base flow index	BFI	Generally, the contribution of groundwater flow to river runoff as a ratio; the higher the contribution the higher the BFI value
Daily mean flow	DMF	Mean river flow (in $m^3 s^{-1}$) in a water-day (09.00 to 09.00 GMT). Typically, flows are calculated on the basis of measurements at 15-minute intervals
Extended end-member mixing analysis	E-EMMA	The use of water quality monitoring data to generate plots of flux of a chemical analyte against flow which may be used to infer and quantify analyte retention and/or release within a river catchment
Ecological quality ratio	EQR	This determines the P concentration at the lower class boundary for each ecological class under the WFD (i.e. high, good, moderate, poor)
Flux		mass area^{-1} time^{-1}
Good Ecological Status	GES	The aspiration of the WFD (see below) that all surface waters reach this status by 2015
Load		mass time^{-1}
Method 3		Load estimation algorithm from Littlewood.[1] Defined in section 2.3
Method 5		Load estimation algorithm from Littlewood et al.[2] Defined in section 2.3
Orthophosphate-P		Generic term used in the current study to describe P concentrations measured for regulatory purposes
Phosphorus Limiting Concentrations	PLC	River phosphorus concentration below which algal growth is nutrient limited
Population equivalent	pe	
Q_{95} flow		Flow (in $m^3 s^{-1}$) which was equalled or exceeded for 95% of the flow record
Reactive phosphorus	RP	Fraction of phosphorus passing through a 0.45 µm filter membrane and measured by the phosphomolybdenum blue colorimetric method
Sewage treatment works	STW	
Soluble reactive phosphorus	SRP	Fraction of phosphorus measured by the phosphomolybdenum blue colorimetric method after settling of suspended particles from the river water sample
Water Framework Directive	WFD	
Water Information Management System	WIMS	A chemical dataset collected and compiled by the Environment Agency of England

40

Abstract

Excess dissolved phosphorus (as orthophosphate-P) contributes to reduced river water quality within Europe and elsewhere. This study reports results from analysis of a 23-year (1990–2013) water quality dataset for orthophosphate-P in the rural Taw catchment (SW England). Orthophosphate-P and river flow relationships and temporal variations in orthophosphate-P concentrations indicate the significant contribution of sewage (across the catchment) and industrial effluent (upper R. Taw) to orthophosphate-P concentrations (up to 96 %), particularly during the low flow summer months when maximum algal growth occurs. In contrast, concentrations of orthophosphate-P from diffuse sources within the catchment were more important (> 80 %) at highest river flows. The results from a 3 end-member mixing model incorporating effluent, groundwater and diffuse orthophosphate-P source terms suggested that sewage and/or industrial effluent contributes $\geq$ 50 % of the orthophosphate-P load for 27 – 48 % of the time across the catchment. The Water Framework Directive (WFD) Phase 2 standards for reactive phosphorus, introduced in 2015, showed the R. Taw to be generally classified as Poor to Medium Ecological Status, with a Good Status occurring more frequently in the tributary rivers. Failure to achieve Good Ecological Status occurred even though, since the early-2000s, riverine OP concentrations have decreased (although the mechanism(s) responsible for this could not be identified). For the first time it has been demonstrated that sewage and industrial effluent sources of alkalinity to the river can give erroneous boundary concentrations of orthophosphate-P for WFD Ecological Status classification, the extent of which is dependent on the proportion of effluent alkalinity present. This is likely to be a European – wide issue which should be examined in more detail.

Keywords: Taw, orthophosphate-P, time series, loads, phosphorus standards, water quality.

4

1 Introduction

The deleterious impacts of increased anthropogenic loads of phosphorus, principally as orthophosphate-P, on river water quality within Europe and elsewhere have been recognised for several decades.[3] Within the EU, the Urban Waste Water Treatment Directive (UWWTD, 91/271/EEC) has been the main legislative driver in reducing phosphorus inputs from urban centres to surface waters, largely via improved waste water collection and reductions in phosphorus concentrations in sewage treatment work (STW) effluents.[4] Across the EU, decreases in riverine orthophosphate-P concentrations of 2.1 % per year on average in the two decades to 2012 have been ascribed to the mitigation measures implemented under the UWWTD.[5, 6] The mean orthophosphate-P concentration in ca. 1000 EU rivers in 2012 was 0.06 mg P L^{-1}.[5] In the UK, decreasing concentrations since the late 1990s – mid 2000s have been reported for the R. Thames[7, 8] and its tributaries[8], and the Dorset R. Frome.[9, 10] In the R. Tamar (southwest England) decreasing concentrations with time were also evident, although reduced sampling frequency in the later stages of the time series reduced confidence in this conclusion.[11]

The EU Water Framework Directive (WFD; 2000/60/EC) was promulgated with the significant objective to protect, enhance and restore all bodies of surface water with the aim of achieving Good Ecological Status (GES) of surface and ground waters by 2015. Despite the apparent success in reducing riverine orthophosphate-P concentrations there are still many rivers across the EU that are failing to achieve GES for this nutrient, including many in the UK.[4] Surface waters receiving effluents from major UK urban centres have been most impacted, and it is here that most effort has been applied to reduce nutrient inputs from STWs (e.g.[7]). In rural catchments with relatively low human populations, however, it has become increasingly apparent that sewage effluents also make an important contribution to riverine orthophosphate-P concentrations, particularly during the lower flow, spring and summer

months when in-river algal growth can flourish.[8, 9, 12, 13] While tertiary nutrient stripping is being installed in larger STWs, most STWs in rural catchments are too small for this to be required. Furthermore, septic tanks remain integral to waste disposal for many dwellings in rural areas, and their not insignificant contribution to nutrient loading in surface waters is now recognised.[14]

The river phosphorus (termed reactive phosphorus) concentrations which define the Ecological Status boundaries prescribed in the WFD Phase 2 standards introduced in 2015 are estimates of natural phosphorus concentrations, taking into account the alkalinity (measured as $CaCO_3$) of the river water and the altitude, above sea level, that would be expected in the absence of anthropogenic pressures.[15-16] The hypothesis is that the alkalinity concentration observed is a reflection of natural rock weathering and hydrological processes. In pristine areas, unperturbed by anthropogenic impacts, this is likely to be correct. However, in rivers receiving sewage and industrial effluents, this hypothesis is incorrect, as these effluents can contain substantial quantities of alkalinity (e.g.[17,18]). In these rivers, inclusion of sewage alkalinity will serve to increase the concentration of phosphorus defining each Ecological Status boundary, effectively providing a more 'relaxed' standard. The extent of this effect will depend on the relative loads of alkalinity from sub-soil sources and sewage and industrial effluent in a sample; for the same effluent alkalinity load the effect will be less for rivers fed from a chalk aquifer than for rivers fed by low alkalinity groundwater or rivers of low base flow index (BFI). The effect may also be most pronounced in rivers which are dominated by effluent flows during the low river flow periods that typify the summer algal growing season.

The Taw catchment in south west England is a predominantly rural environment with a low population and little industry. Nevertheless, thirteen water bodies across the catchment were failing GES for phosphorus under the WFD Phase 1 cycle.[19] An important aim of the

6

116   Taw River Improvement Project, a recently completed 2.5 y £1.86 M programme designed to

117   improve ecological status of rivers across the catchment (L. Couldrick, pers. comm.) was to

118   undertake an assessment of river water quality data for phosphorus in the catchment. This

119   study is a contribution to that aim. The specific objectives for the current study were to: (i)

120   quantify temporal trends in orthophosphate-P concentrations between 1990 and 2013, and to

121   apportion orthophosphate-P sources, and (ii) calculate Ecological Status in relation to

122   orthophosphate-P using the WFD Phase 2 standards, and then examine if the effluent

123   component of alkalinity compromises the standards for orthophosphate-P in this catchment,

124   and by implication in catchments across the EU. The second objective provides the first

125   analysis of its kind.

2 Methods

2.1 Study area

The Taw system is part of the North Devon catchment of the UK South West River Basin District[20] and covers an area of 1211 km^2. The R. Taw rises at Taw Head on Dartmoor (altitude 550 m AOD) and flows northward to join the estuary at the tidal limit at Newbridge. The major tributaries are the Mole, the Lapford Yeo and the Little Dart River (Fig. 1). The R. Taw (68 %) and the R. Mole (29 %) drain 97 % of the catchment (Table 1). The mean, maximum and Q_{95} flows reflect the relative size of the drainage basins, with these values highest at Umberleigh, located closest to the tidal limit (Table 1). The river responds quickly to rainfall, with rapid rises in river levels.[21] The river base flow indices are mid-range (0.42 – 0.47; Table 1), and alluvial deposits in the main river valley may contribute to river flows during dry periods.[21] Catchment geology is dominated by the Carboniferous Bude and Crackington formations, while > 95% of the catchment is covered by clay and clay loam soils.[22] About 75% of the catchment area is used for agriculture (59% grassland, 14% arable), 12% woodland and forest and 9% rough grassland.[23] An estimated 77% of the grassland is used for beef cattle and sheep, whilst the remainder is used for dairy cattle.[22] The main areas of population are Barnstaple (population 47858 in 2009), Braunton (11491), South Molton (13576) and Witheridge (2262), as shown in Fig. 1.

2.2 Data resource and general approach

Daily mean river flows (DMFs; calculated from 15 min interval instantaneous flow data over 24 h) were obtained from the Environment Agency (EA) gauging stations (GS) at Umberleigh and Taw Bridge on the R. Taw and Woodleigh on the R. Mole (Table 1 and Fig. 1) from 1990 onwards. Chemical determinand data from 1990, collected for statutory monitoring purposes, were also obtained from the EA WIMS for the sampling sites shown in Fig. 1 and detailed in Supplementary Information (SI) 1. Site selection was based on EA

151   evidence, since 2010, of failure of river waters to meet WFD Phase 1 GES for

152   orthophosphate-P because of effluent and diffuse pollution.[19] Sample record end dates

153   occurred between 2006 and 2013, depending on site (SI 1). The chemical determinands

154   considered herein are orthophosphate-P and total alkalinity. Orthophosphate-P was

155   determined in the sample supernatant following settlement of suspended particles originally

156   present in the collected water sample. As the supernatant may contain colloids and fine

157   particles, as well as non-orthophosphate 'dissolved' P, the resulting measured P

158   concentrations may represent orthophosphate-P plus P associated with these other

159   components that is measurable by the analytical technique used. As a result, the

160   orthophosphate-P as it is coded in the EA database, may be variously referred to as soluble

161   reactive phosphorus (SRP) or reactive phosphorus (RP). In this paper the term

162   orthophosphate-P is used by default, although the other terms are used when appropriate.

163   For sites sampled between 1990 and 2013, water samples were collected from a

164   maximum of 4.3 % of the 8766 gauged flow days. In general, 4 % of the chemical samples

165   were collected within 7 days of each other, 15 % within 14 days and 57 % within 30 days.

166   Relatively high frequency sampling (25-35 samples y^{-1}) was undertaken between 1991 and

167   1996 at site 2; otherwise the frequency at this site and elsewhere was 10-13 samples y^{-1}.

168   Effluent data for sewage treatment works (STWs) in the catchment were provided by the EA;

169   the orthophosphate-P concentration was 5.3 mg P L^{-1} (in the centre of the range of 1 - 10 mg

170   P L^{-1} for UK sewage effluent[24]) while dry weather flows for each STW were given as an

171   annual mean. The EA also provided effluent orthophosphate-P concentration and flow data

172   for the Taw Valley Creamery, located in the upper catchment between sites 9 and 10 (see Fig.

173   1), for 2006 – 2014. There are also many septic tanks throughout the area, which can act as

174   either point or diffuse inputs for nutrients[14], but there were no data on either flows or nutrient

175   concentrations available for these potential sources.

176   In section 3 the data are generally reported for the R. Taw and its tributaries

177   separately. However, at three locations (two on the R. Taw and one on the R. Mole), river

178   flow and chemical concentration data were integrated at each of these locations individually

179   to provide additional insights into orthophosphate-P behaviour; subsequently, the results from

180   these three locations are discussed as a group. For the first location, the flow data from site 3

181   were combined with the chemical data from site 2, and for the second location chemical data

182   for site 14 were combined with flow data for the Woodleigh GS on the R. Mole. Site 3 is ca.

183   4.5 km upstream of site 2, the most frequently sampled site on the R. Taw, while the

184   Woodleigh GS is ca. 4 km upstream of site 14. For the third location, the Taw Bridge GS is

185   co-incident with the chemical sampling at site 7 (Fig. 1). These locations are therefore

186   referred to as site 2, site 14 and site 7. In addition to orthophosphate-P there is also a more

187   extended treatment of the alkalinity data because of the key role of this parameter in the

188   definition of river water quality standards for phosphorus within the WFD.

189   **2.3 Temporal trend statistics and load estimation algorithms**

190   Exploratory data analysis indicated that there appeared to be decreasing trends in

191   orthophosphate-P concentrations in the time series at sites 2, 7 and 14, particularly from ca.

192   2003 onwards. To quantify the potential significance of these patterns at each individual site,

193   temporal trend analyses using the Spearman's Rho, Mann-Kendall and Seasonal Kendall

194   tests were undertaken. These tests are non-parametric, rank-based statistics designed to

195   reveal gradual monotonic trends in time-series data[25,26] and are appropriate for relatively

196   coarsely-resolved data.[27]   The theoretical basis of the trend statistics are described in Hipel

197   and McLeod and Helsel[25] and Hirsch.[28] The Seasonal Kendall test performs the Mann-

198   Kendall test for individual seasons of the year, where season is defined by the user.[26] The

199   Mann-Kendall and Seasonal Kendall tests require the data to show constant variance through

200   time and to not show autocorrelation.[26,28] Log_{10} transformation of the orthophosphate-P

201   variable satisfied the first assumption, while autocorrelation function analysis showed that the

202   orthophosphate-P data were largely within the limits of acceptable autocorrelation.

203   Autocorrelation is less likely to be observed in monthly resolved data of up to 10 years

204   duration, as is the case here.[26,27] Trend analyses were undertaken on both non flow-adjusted

205   orthophosphate-P concentrations (representing the influence of both hydrological and non-

206   hydrological factors) and flow-adjusted orthophosphate-P concentrations (representing non-

207   hydrological factors only), following Hirsch et al. [29] and Jaruskova and Liska.[30] Human

208   related activity may account for a proportion of the latter.[31] For the flow-adjusted analyses,

209   temporal trend analyses were undertaken on residuals obtained from ordinary least squares

210   linear regression of orthophosphate-P concentration vs flow. The data were $\log_{10}$ transformed

211   prior to regression in order to ensure regression residuals were homoscedastic in each of the

212   three cases, although Hirsch et al. [29] had previously defended the use of the parametric

213   procedure by stating that it was used only to remove variance explained by the flow variable,

214   rather than using it for statistical modelling per se. The significance of all temporal trend

215   results were tested at $\alpha = 0.05$. The Spearman's Rho tests were undertaken using Sigmaplot®

216   11, while the Mann-Kendall and Seasonal Kendall tests were undertaken using an executable

217   file developed by, and downloaded from, the US Geological Survey.[26] Significance of the

218   correlation coefficients was tested at the $p < 0.05$ level. Autocorrelation function analyses

219   were undertaken using Minitab®17.

220   The estimation of orthophosphate-P loads (mass time^{-1}) reported in the current work

221   are based on the following algorithms:

222   (i) the quantitation of the low (or base) flow end member load, and its division into a

223   groundwater and an effluent contribution follows the extended end-member mixing analysis

224   (E-EMMA):[3]

225          $L_{baseflow} = L_{effluent} + L_{groundwater}$ Eqn (1)

226 $$L_{effluent} = \Sigma(C_{stw}, Q_{dwf\_stw})$$ Eqn (2)

227 $$L_{groundwater} = C_{groundwater} \times Q_{groundwater}$$ Eqn (3)

228 $$Q_{groundwater} = Q_{river\_min} - Q_{effluent}$$ Eqn (4)

229 $$Q_{effluent} = \Sigma Q_{dwf\_stw}$$ Eqn (5)

230 where L is determinand load in g s^{-1}, C is determinand concentration in g m^{-3}, Q is flow in m^3

231 s^{-1}, dwf_stw is sewage treatment work dry weather flow and river_min is the minimum daily

232 mean river flow for the period of interest.

233 (ii) Method 5 is the favoured OSPARCOM algorithm for estimating determinand loads from

234 periodic concentration and flow data; the load, L, is flow-weighted.[2]

$$L = \left(\frac{K \sum_{i=1}^{n}(Q_i\, C_i)}{\sum_{i=1}^{n} Q_i} \right) \overline{Q}$$ Eqn (6)

235 C_i is the deteminand concentration (in g m^{-3}) in each of i = 1, n samples, Q_i is the

236 corresponding daily mean river flow for that sample. K is 86400 seconds per day and the load

237 L is g d^{-1}. $\overline{Q}$ is the flow-weighted term and is given by:

$$\frac{\sum_{k=1}^{N} Q_k}{N}$$ Eqn (7)

238 where Q_k represents daily mean river flows for each day of the year (k = 1, N) and N is the

239 number of days in the year.

240 (iii) Method 3 defined the load as:

$$L = K \sum_{i=1}^{n} (C_i\, \overline{Q}_p)$$ Eqn (8)

241 where $\overline{Q_p}$ is the mean flow for the period between samples.[1]

3. Results and Discussion

3.1 Spatial and temporal variability in orthophosphate-P concentrations

3.1.1 Spatial variability

The annual spatial and temporal variability in the concentrations (mean ± one standard deviation) of orthophosphate-P for the R. Taw are summarised in SI 2. Concentrations were relatively low in the upper R. Taw at site 11 (generally < 0.04 mg P L^{-1}), became markedly higher downstream, 0.089 – 0.707 mg P L^{-1} at site 9, and then decreased further downstream to 0.036 – 0.186 mg P L^{-1} at site 2, located close to the tidal limit at site 1. The lower concentrations are typical of rural sites in southwest England showing some evidence of anthropogenic impact.[6, 10, 11] The elevated concentrations observed at sites 7, 8 and 9 were more typical of urban areas impacted by effluents[32,33], and were likely to have been due to effluent discharged from the Taw Valley Creamery and STWs located on the upper R. Taw (North Tawton, Belstone/South Tawton; see Fig. 1). Incorporation of effluent orthophosphate-P concentration and flow data from the Creamery and the STWs into a conservative dilution model for the short stretch of river reach between Belstone/South Tawton and Taw Bridge (distance ca. 12 km) indicates that the Creamery effluent may have been a significant contributor (up to 100 %) to the orthophosphate-P concentration observed at site 7 (Taw Bridge), as shown in Fig. 2. Nevertheless, the STW (population equivalent (p.e.) 2706) also was important, particularly during the summer.

The annual mean concentration data for orthophosphate-P in tributary rivers are given in SI 3. As for the R. Taw, mean concentrations varied by an order of magnitude across the 16 sites, and variations in concentrations about the mean were large at many sites. The relatively high concentrations at site 12, on the R. Mole, were probably due to effluent discharges from the STWs located upstream at South Molton and North Molton; the former is the second largest STW in the catchment and together they have an estimated P load of 2.75 t

267 y^{-1}, equivalent to 26 % of the STW effluent P loads to rivers across the entire catchment.

268 Downstream of site 12, orthophosphate -P concentrations decreased (sites 13 and 14),

269 presumably due to dilution and/or loss of nutrient from solution. In addition, the tributaries

270 draining into the Mole upstream of site 13, at sites 15 and 16, were low in orthophosphate-P.

271 Sites 19 - 25 showed wide variability in mean concentrations. In this region there are a

272 number of STWs, with an aggregate p.e. of over 3000 and an effluent P load of ca. 1.4 t y^{-1},

273 and it is likely that these inputs would have contributed to this variability. Lowest mean

274 concentrations occurred at site 18, and at sites 26 and 27 located in the more northerly part of

275 the catchment.

276   A decreasing concentration of any dissolved determinand with increasing river flow

277 (the type 1 response[10]) can be largely explained by the dilution of determinand rich effluents

278 or groundwater, or both, with determinand poor diffuse run-off from the catchment. The

279 concentration – flow relationships for orthophosphate-P at sites 2, 7 and 14 exemplify this

280 behaviour (SI 4(a)). Recasting the orthophosphate-P data as a monthly time series, shown in

281 SI 4(b), similarly reveals that the highest concentrations (and largest standard deviations in

282 concentrations) consistently occurred during the low flow, summer months. Thus, the

283 maximum mean concentrations occurred in September at site 7 (0.94 ± 1.09 mg P L^{-1}), in

284 August at site 2 (0.13 ± 0.09 mg P L^{-1}) and in July at site 14 (0.07 ± 0.05 mg P L^{-1}).

285 **3.1.2 Temporal trends**

286   The results of the temporal trend analyses are reported in Table 2. While the

287 correlation coefficients are weak to moderate (ca. -0.3 to -0.5), all three tests show that for

288 each site there was a significant downward trend in orthophosphate-P concentrations over the

289 sampling periods, for both the flow adjusted and non-flow adjusted data. However, the

290 similarity in the magnitude of the correlation coefficients from analyses on the flow adjusted

291 and non-flow adjusted concentrations indicates that hydrological variability may have played

14

292   a role. There have been changes to river water abstractions and augmentation in the Taw

293   catchment (as noted in Table 1) although it is not possible to attribute any of the changes in

294   orthophosphate-P concentrations to these factors. It has been shown that median (Q_{50}) flows

295   during the summer and autumn (June – November) for the period 1969 – 2008 increased by

296   10 – 30 % in the southwest of England, probably due to climatic factors.[34] In principle,

297   increased river flows during summer and autumn would, inter alia, lead to increased dilution

298   of the point source orthophosphate-P loads that tend to dominate during these periods, and

299   hence give rise to lower river orthophosphate-P concentrations. This may explain, to some

300   extent, why the Seasonal Kendall test returns larger positive correlations in each case than the

301   Mann Kendall test, which doesn't explicitly account for seasonal scale changes in the data

302   (Table 2). However, this hypothetical scenario is likely to be confounded by the complexity

303   of catchment nutrient cycling, sources and losses, and their changes with time. Recent

304   decreases in orthophosphate-P concentrations observed in English rivers in the last decade or

305   so have been due to nutrient stripping of STW effluents prior to final discharge.[7, 10, 35, 36] In

306   the Taw catchment, orthophosphate-P stripping has not been implemented under the

307   UWWTD because of the relatively small sizes of the individual STWs within the catchment,

308   and so the downward trends in orthophosphate-P concentrations cannot be ascribed to this

309   driver. Reductions in P-loading of domestic detergents may have played a role[37], but as

310   temporal trend data for effluent P loads from STW in the catchment were not available, this

311   suggestion is tentative. The downward trend may also be explained, in part, by changes in

312   P_2O_5 fertiliser applications over the last decade; for grassland in southwest England,

313   applications have decreased by ca. 30 % since 2002, to 7 kg ha^{-1} P in 2013, while for all crops

314   and grass the inputs have halved over the same period to 14 kg ha^{-1} P in 2013.[38, 39] An

315   additional factor that could generate an apparent trend in decreasing orthophosphate-P

316   concentrations is a change to lower resolution sampling and subsequent flattening of the

317 signal.[40-42] In the current study, the apparent downward trends in concentrations observed

318 from the early-2000s was not accompanied by a clear change in sampling frequency, and so

319 the trends, if real, were due to factors that are unidentified at present. The potential

320 consequences for improved ecological status of these apparent reductions in orthophosphate-

321 P concentrations, in relation to phytoplankton growth and community composition, are

322 examined in section 3.3.

323 **3.2 Orthophosphate-P sources and loads**

324 **3.2.1 Catchment integrated diffuse sources**

325 The approximately asymptotic decrease in orthophosphate-P concentrations as flows

326 increased, described in section 3.1.1, can provide information on the integrated diffuse (run-

327 off from the surface and unsaturated zone that could include agricultural and septic tank

328 sources[35, 43]) orthophosphate-P contribution from the catchment to the river. A quantitative

329 estimate of this contribution can be derived from the gradient of the regression of

330 orthophosphate-P load vs flow.[43, 44] The underlying assumption of this approach is that an

331 increase in orthophosphate-P load is due only to this diffuse term, while loads from other

332 important sources (groundwater and STW/industrial effluent) remain uniform regardless of

333 overall river flows.[9, 44] We do not have the data to test this assumption however, as is outlined

334 in section 3.2.2. In the current work, concentration and flow data for all years at each site

335 have been used for the quantitation because annual sampling frequency was generally low

336 (10-13 samples y^{-1}). Thus, the results reflect an integration of all the spatial and temporal

337 variation in inputs across the catchment plus any in-water orthophosphate-P gain/loss that

338 may have occurred (e.g.[43]). In an earlier study[44] ordinary least squares regression (OLS) was

339 used to quantify the relationship between load and flow. However, in the current work a

340 robust linear regression (bisquare weight method) has been used to quantify the relationship

341 as this technique is less sensitive than OLS to heteroscedasticity in the data and the presence

342 of outliers.[45] The results of the regression analyses are reported in SI 4(c) for sites 2 and 14

343 which represent the riverine outlets from the Taw and Mole sub-catchments. The

344 relationships between load and flow at both sites are significantly (p < 0.001) and positively

345 linearly correlated, with R^2 values of 0.93 and 0.95, respectively. The slopes of the lines

346 indicate that the Taw and Mole sub-catchment contributions to orthophosphate-P

347 concentrations were of the order 0.035 mg P L^{-1} (0.034 – 0.036 mg P L^{-1}, 95 % CI) and 0.019

348 mg P L^{-1} (0.018 – 0.021 mg P L^{-1}, 95 % CI), respectively. In order to reveal variability around

349 these 1990-2013 integrated values, separate regressions between load and flow were

350 undertaken for site 2 for 1991 to 1996 when sampling was more frequent (25-35 samples y^{-1}).

351 In all cases the R^2 values were strongly positive (range 0.75 - 0.94) and slope values (mean

352 0.054 mg P L^{-1} and range 0.029 – 0.076 mg P L^{-1}) similar to or higher than the concentration

353 shown in SI 4(c). It is noteworthy that the reported year on year reductions in fertiliser P

354 loads have not obviously influenced the catchment integrated diffuse loads of

355 orthophosphate-P. This de-coupling, if real, may simply be a reflection of complexity in the

356 mobilisation and transfer of phosphorus at large areal scales.[46] The diffuse catchment

357 concentrations estimated here are similar to those observed for the rural R. Tamar catchment

358 (southwest England) (range 0.025 – 0.118 mg P L^{-1}) but lower than those calculated for the

359 urbanised R. Thames and R. Thame catchments (southeast England) (range 0.097 – 0.298 mg

360 P L^{-1}).[11, 36]

361   The approximately conservative behaviour of orthophosphate-P evidenced by the

362 positive and significant coefficients of determination in the load vs flow plots in SI 4(c) is

363 perhaps counter-intuitive given the multitude of orthophosphate-P sources across the

364 catchment, the downward temporal trend in river orthophosphate-P concentrations and

365 known in situ orthophosphate-P reactivity in rivers.[3, 43] With respect to in situ reactivity,

366 exchange of phosphorus between river bed sediments, pore waters and overlying waters in

367 the upper Taw river and tributaries has been reported to be limited.[47] In addition, within-river

368 P cycling was unimportant relative to the source loadings of orthophosphate-P in the Dorset

369 R. Frome, located in southern England.[9] A more rigorous assessment of orthophosphate-P

370 behaviour (i.e. conservative, non-conservative) is desirable, but this would require higher

371 temporal sampling resolutions (daily, weekly) than the monthly sampling adopted by the

372 EA.[3]

3.2.2 Sources and loads at river base flow

374 Equations (1) – (5), given in section 2.3, were used to quantify the low (or base) flow

375 end member loads of orthophosphate-P from groundwater and effluent. There are no direct

376 measurements of groundwater orthophosphate-P concentrations in the Taw catchment, but

377 typical concentrations of total dissolved phosphorus (orthophosphate-P + refractory inorganic

378 P + organic P) in a wide range of English groundwaters, including from the nearby Dartmoor

379 granite, are < 0.1 mg P L^{-1}.[48, 49] Incorporation of the groundwater (0.1 mg P L^{-1} used for

380 concentration) and STW flow and concentration data into equations (1) to (5) revealed that

381 STW effluent could theoretically contribute 96 %, 85 % and 72 % of the orthophosphate-P

382 load at site 7 (the Creamery effluent was included for this site; median P concentration is 5.5

383 mg L^{-1}), site 2 and site 14, respectively, during lowest river flows. The estimated dominance

384 of the effluent signal at site 7 is in good agreement with the results from the dilution model

385 assessment shown in Fig. 2. From this perspective, i.e. the dominance of effluent

386 orthophosphate-P at low river flows, the Taw is typical of rivers across the UK.[10, 13, 35, 36, 43, 44]

3.2.3 A source apportionment model for orthophosphate-P

388 The catchment integrated diffuse source concentrations of orthophosphate-P reported

389 in section 3.2.1 were combined with the orthophosphate-P loads from effluents and

390 groundwater calculated in section 3.2.2 to give a source apportionment model (SAM) that is

391   analogous to the Type 1 E-EMMA described in [3]. This three end-member load mixing model

392   can calculate the contribution of each source (effluent, groundwater, catchment) to the overall

393   orthophosphate-P load as river flow increases. As such, the SAM can be viewed as an initial,

394   pragmatic, attempt to examine the relative importance of orthophosphate-P loads under

395   contrasting flow regimes, and provides a basis for more detailed studies of orthophosphate-P

396   loads if or when higher temporal resolution orthophosphate-P concentration data become

397   available. In the SAM the same assumption was made regarding changes in load as given in

398   section 3.2.1, that only the diffuse loads increased with flow (thus for each 1 m^3 s^{-1} increase

399   in flow the diffuse load would increase by 0.035 g P s^{-1} and 0.019 g P s^{-1} for the Taw and

400   Mole sub-catchments, respectively). The results from the SAM are given in Fig. 3. At the

401   lowest flows, effluent loads dominate (72 – 85 %) at the outlets of the Taw and Mole sub-

402   catchments (consistent with the loads estimated using equations 1 - 5), while groundwaters

403   contribute 15 – 28 %. At the highest river flows, in contrast, diffuse loads dominate (91 -

404   93 %) and effluent loads are only ca. 6 % of the total. Nevertheless, effluent orthophosphate-

405   P contributes ≥ 50 % of load for approximately a half and a quarter of the time in the Taw

406   and Mole, respectively; which again emphasises the importance of effluent orthophosphate-P

407   during the critical low-flow, algal growing season.

408   **3.2.4 Loads derived from EA WIMS data**

409   Orthophosphate-P loads at each of the gauged sites were also calculated directly from

410   river flow and EA WIMS monitoring data for the days for which orthophosphate-P data were

411   available. Concentrations given as less than (these were << 1 % of the total dataset) were

412   divided by 2 for the calculation.[50] The favoured OSPARCOM approach for load estimation

413   was used[2] (the flow weighted Method 5, equation (6) in section 2.3). Mean and median daily

414   load values were then calculated for each year, and the results are shown in Fig. 4(a). In each

415   case the mean loads were similar to or larger than the median loads; the largest differences

416 were observed at site 7, presumably because of the occurrence of enhanced orthophosphate-P

417 concentrations at this site (SI 2). Highest mean loads were observed at site 2 and were in the

418 range 34 – 191 kg P d^{-1}, reflecting the relatively large size of its drainage area and hence river

419 flows. The next highest loads occurred at site 7 (12 – 116 kg P d^{-1}). Loads from site 14 on the

420 R. Mole were in the range 20 – 60 kg P d^{-1} and showed much less annual variation than the R.

421 Taw sites. The magnitude of the loads decreased in the latter half of the time series, a trend

422 that is consistent with the reduction in concentrations described in section 3.1.2. The trend of

423 decreasing loads is particularly marked at site 7 in the upper R. Taw and site 14 on the R.

424 Mole.

425   Bowes et al.[40] calculated loads of SRP in the high BFI (0.84) R. Frome (southern

426 England) using an algorithm assessed to be the most accurate (lowest bias) and least

427 imprecise (Method 3, equation 8 in section 2.3). Based on monthly sampling, bias in annual

428 load estimates for SRP in the R. Frome were in the range -10.6 to + 12.2 % (with one at

429 +27.9 %) relative to the 'true' load calculated from more frequently collected samples

430 (average 3.7 samples per day for one year). Load bias may be greater in the Taw because it is

431 a lower BFI (0.43) catchment, although because it also has a low population density, this may

432 not necessarily be the case.[41] Load estimates for total reactive phosphorus (equivalent to

433 orthophosphate-P in the current work) using EA monitoring data (6 samples y^{-1}; May 2011 –

434 September 2012), using the Method 5 algorithm, gave a bias of + 7.1 % compared with

435 higher resolution (hourly) data, in the low BFI (< 0.50) R. Leith (northwest England)

436 catchment.[51] However, loads calculated during periods dominated by either low or high river

437 flows showed much poorer agreement with the high sample resolution based loads, implying,

438 inter alia, that the data record timespan used for inter-comparisons is important. Indeed, it has

439 been shown that high resolution sampling is necessary in order to quantify short term

440 variability in orthophosphate-P concentrations and hence loads.[40] From these studies it can be

441   concluded that the load estimates given in the current work may have a bias of up to ± 20 %.

442   Maier et al.[52] reported the average orthophosphate-P load at Umberleigh (site 3 in the current

443   study) to be 37 t y^{-1} for the period 1990 – 2004. Extrapolation of our estimates at site 2 to an

444   annual basis gives an average of 44 t y^{-1} over the same period and 38 t y^{-1} over the longer

445   period of 1990 – 2013 examined herein, both of which are within the bias error given above.

446   A comparison of the loads derived from the EA WIMS monitoring data and the SAM

447   was undertaken for sites 2 and 14. The EA derived mean and median loads for each year were

448   plotted against the mean river flow for the year (the latter calculated from the flow weighted

449   Method 5) and compared against the SAM calculated loads for the same flow range; the

450   results are presented in Fig. 4(b). While the SAM calculated loads increase monotonically

451   with flow (because only river flow changes in the model) they fall centrally within the ranges

452   calculated using Method 5 for both sites. This agreement indicates that the inclusion of

453   temporally variable orthophosphate-P loads into the SAM would improve the correlation

454   between these two load estimation approaches. Diffuse load data for orthophosphate-P at site

455   2 (cf. SI 4(c)) were calculated separately for the years 1991 to 1996 when sampling frequency

456   was relatively high (25 – 35 samples y^{-1}), and the modelled loads recalculated for each of

457   those years (< 8 % of the data used to calculate the diffuse values were excluded as outliers).

458   Subsequent bisquare weight linear regression of EA derived median loads against SAM

459   calculated loads gave an R^2 of 0.91 and a slope of 1.23 (n = 5, 1995 excluded). Although n is

460   small, this good fit indicates that the approach used for estimating the diffuse concentration,

461   exemplified in SI 4(c), is robust and that, on an annual basis, the estimated loads calculated

462   by the two methods are not likely to be significantly different given that the bias (23 %) is of

463   a similar order to the bias in orthophosphate-P load estimations reported previously.[40,51]

464   While this agreement is encouraging, the advantage of the SAM approach, relative to the

465 Method 5 load estimation, is the ability to separately identify the diffuse and point load

466 components.

467   The load estimation approaches described in sections 3.2.1 to 3.2.4 can be

468 summarised and linked in the following way. Base flow orthophosphate-P loads from

469 groundwater and effluents revealed that at lowest river flows, effluent contributed 72 – 96 %

470 of the load at the three sites examined. Data from the base flow loads and integrated

471 catchment inputs of orthophosphate-P were combined to give a source apportionment model

472 which showed that effluent orthophosphate-P contributed at least half of the orthophosphate-

473 P load for 27 – 48 % of the time. This outcome is consistent with recent reports of the

474 importance of effluent orthophosphate-P at low river flows in other English catchments

475 (e.g.[10]). Orthophosphate-P loads were also calculated from EA WIMS data using the

476 OSPARCOM Method 5 and compared with the loads derived from the SAM. The proximity

477 between the load estimates derived from the two approaches appeared to be of the same

478 magnitude as the bias in orthophosphate-P loads reported for other lower BFI English

479 rivers.[51] It is anticipated that inclusion of more highly temporally resolved data would

480 improve the agreement between these two load estimation approaches, although there appear

481 to be a dearth of studies on the relationship between sampling frequency and orthophosphate-

482 P load uncertainties in effluent impacted low BFI UK rivers.

483 **3.3 Water quality**

484 **3.3.1 Water Framework Directive Phase 2 standards for reactive phosphorus**

485   Site specific standards for reactive phosphorus (RP) under Phase 2 of the WFD

486 standard setting process were implemented in 2015.[16, 53] In Phase 2, RP is defined as

487 phosphorus that will pass through a 0.45 μm pore size filter membrane and can be measured

488 by the phosphomolybdenum blue colorimetric method.

489   The RP standard, which is a calculated annual mean concentration, is defined by

490   equation (9):

491   RP standard (μg P L^{-1}) = 10^((1.0497 $\log_{10}$(EQR) + 1.066) * ($\log_{10}$(reference

492   condition RP) – $\log_{10}$(3500)) + $\log_{10}$(3500))   Eqn (9)

493   The RP standard is the concentration estimated for the lower class boundary of the High,

494   Good, Moderate and Poor Ecological Status. The Ecological Status depends on the value of

495   EQR used, where EQR is the site independent ecological quality ratio at the class

496   boundary.[15, 16] The 'reference condition RP' is the RP concentration expected at near natural

497   conditions, subject to local geology and geography. It can be estimated as:

498   Reference condition RP = 10^(0.454($\log_{10}$alkalinity) – 0.0018(altitude) + 0.476)   Eqn (10)

499   Alkalinity is the mean annual total alkalinity (mg $CaCO_3$ L^{-1}) of the water (a proxy for

500   geology and location) at a given site and the altitude is height (in m, AOD). The annual

501   spatial and temporal variability in the concentrations (mean ± one standard deviation) of

502   alkalinity for the R. Taw and the tributary rivers are summarised in SI 5 and SI 6,

503   respectively. There were no clear temporal trends in mean annual concentrations of alkalinity

504   across the catchment, but there were marked spatial differences. On the R. Taw there was a

505   notable increase in alkalinity concentrations in the upper catchment between site 10 and the

506   downstream site 9. This pattern, and indeed the trends in the remainder of the R. Taw,

507   mirrored those of orthophosphate – P. In the tributary rivers, the highest mean concentrations

508   occurred at sites 22 – 25 and to a lesser extent at sites 19 – 21. It is also noteworthy that the

509   sites with the highest mean concentrations also had the largest standard deviations about the

510   mean concentration.

511   Equations (9) and (10) have been used to retrospectively examine the compliance of

512   the R. Taw and its tributaries with the Phase 2 RP standards and the results are reported in

Fig. 5 and SI 7. For the R. Taw itself, most sites (4, 5, 6, 7, 8, 9) would be classified as 'Poor', while sites 2, 3 and 10 would be classified as 'Moderate' and site 10 occasionally as 'Good'. The ratio of the measured RP to reference condition RP can be calculated for each year for each site and is a quantitation of the human impact on ambient phosphate-P concentrations.[15] The ratio values reflect the range found for Ecological Status, with measured orthophosphate-P concentrations at 'Poor' sites factors of 10 or more above the reference condition, implying marked anthropogenic nutrient pressures at these locations. For the tributary rivers the Ecological Status would be better, with a number of sites achieving 'Good' in some years (sites 14, 15, 16, 18, 26, 27). Nevertheless, sites 19 - 25 appear particularly impacted, with a 'Poor' status dominant and ratios generally > 10.

While there are uncertainties in correlating RP standards with actual biological impacts,[16] it is likely that concentrations of orthophosphate-P in the Taw catchment rivers, particularly during summer, were generally above concentrations considered detrimental to periphyton and benthic diatom communities. Figure 6 shows orthophosphate-P concentrations for the summer growing season (April to September) for two sites on the Taw with the lowest orthophosphate-P values; site 10 in the upper catchment and site 2 at the catchment outlet (for the tributaries, only sites 18, 26 and 27 exhibited similarly low concentrations). Also shown on Fig. 6 are reported Phosphorus Limiting Concentrations (PLC) for some UK and US rivers below which periphyton biomass accrual rates were observed to decline (summarised in [54]). It can be seen that most orthophosphate-P concentrations were in the range of these PLC values, particularly in the later part of the time series. Targeted experiments on the Taw itself would be required to see if a decrease in algal biomass had indeed occurred. As these sites probably represent the best case scenarios it is likely that the remaining sites in the Taw catchment would require more comprehensive mitigation measures in order to achieve GES with respect to orthophosphate-P.

3.3.2 Does the use of alkalinity compromise the phosphorus standards?

Within the WFD Phase 2, the phosphorus-P standards for rivers are dependent on alkalinity and altitude, as described above. In the unperturbed, or 'reference' sites of Phase 2, alkalinity and altitude explain most of the variation in river RP concentrations because these parameters "take into account the main sources and controls of the natural variation in soluble phosphate concentrations (i.e. rock weathering)".[15] Thus the reference conditions are defined by an absence of anthropogenic pressures and indicate that river flows are driven by natural catchment hydrology. The resulting linear regression of alkalinity/altitude with RP is used to calculate the 'expected' concentration of RP at any site in the UK. This value is also used to determine the RP concentrations that delineate the boundaries between the five different Ecological Status classifications, as described in section 3.3.1.

While the Phase 2 RP standards are framed as annual mean concentrations, many studies have highlighted the importance of orthophosphate-P to periphyton and benthic diatom growth during the low flow, summer months.[13, 55] From equation (1) it has been established that low river flows can have contributions from both groundwater and effluents from sewage treatment and industrial sources, and the relative importance of these sources to orthophosphate-P at three sites in the Taw was estimated from equations (1) to (5). This approach can be extended to alkalinity because sewage (and some industrial) effluent contains alkalinity (principally carbonate/bicarbonate, but also borate and organic acids, and orthophosphate-P itself [18]), and so, at low flows, riverine alkalinity will have both a groundwater and an effluent component. Summary plots of alkalinity concentration *vs* river flow and monthly variations in alkalinity concentrations for the sites 2, 7 and 14 in the Taw catchment (Figs. 7(a) and (b), respectively) are consistent with this contention, with the highest concentrations occurring at low flows and during the summer months. Notably, these trends mirror those for orthophosphate-P shown in SI 4(a) and (b).

563   The presence of effluent alkalinity implies that the calculated "reference condition"

564   and "Ecological Status boundary" RP concentrations may be incorrect, the size of the

565   discrepancy being dependent on the proportion of effluent alkalinity. In addition, the

566   calculated RP concentration at a given boundary may be higher in effluent influenced rivers,

567   relative to groundwater dominated rivers, thereby giving a misleading impression of the

568   ecological status of the water body. Separation of the measured alkalinity at low river flows

569   into these two components, using equations (1) to (5), has been done for sites 2, 7 and 14.

570   Box 1 summarises the calculations, including the data used and underlying assumption made.

571   Thus, it has been estimated that ca. 43, 76 and 26 %, respectively, of the measured river

572   alkalinity at these sites was from effluent. Reference condition RP and High/Good RP

573   boundaries were then calculated with and without this effluent component for the

574   ecologically important summer period of April to September (Fig. 8). The measured :

575   predicted RP ratio increased by 29 %, 89 % and 15 % at sites 2, 7 and 14, respectively, while

576   the reference condition RP concentrations decreased by the same margins. The associated RP

577   concentrations delineating the High/Good boundary fell by 26 %, 78 % and 13 %,

578   respectively, at these sites.

579   The significance of these results with respect to nutrient reduction strategies, at this

580   time, should be placed in the context that the Phase 2 standards are for annual mean

581   concentrations of both alkalinity and RP. For example, using the data in Box 1, it is possible

582   to apportion river loads of alkalinity from the different sources (effluent, groundwater,

583   diffuse) against changes in river flow (cf. orthophosphate-P in Fig. 3). The results, shown in

584   Fig. 9, suggest that both effluent and groundwater alkalinity are important at low flows,

585   consistent with the calculations above. Thus, for flows $\leq Q_{95}$ value, effluents may account for

586   25 − 50 % of the alkalinity load for the sites representing the outlets of the Taw and Mole

587   catchments. Nevertheless, because of the paucity of data on flows and concentrations used in

588   this analysis, as noted in footnotes d and e to Box 1, these results probably provide only a

589   first order assessment of the importance of alkalinity sources under contrasting river flows,

590   and in particular at low flows. Additional work using more constrained datasets would serve

591   to reduce the uncertainties and arguably contribute to a more refined set of phosphorus

592   standards for inclusion in a Phase 3 cycle of standards revisions under the WFD.

4. Summary and conclusions

The results from a source apportionment model incorporating effluent, groundwater and diffuse loads of orthophosphate-P suggested that effluent discharged to the rivers in the Taw catchment contributes approximately half of the orthophosphate-P load for up to half of the time across the catchment. However, during the more biologically important summer months, significant contributions of sewage (across the catchment) and industrial effluent (upper R. Taw) to orthophosphate-P concentrations (up to 96 %) occur. These sources probably contribute to the generally Poor to Moderate Ecological Status of the rivers with respect to the recently introduced WFD Phase 2 standards for phosphorus. Since the early-2000s, orthophosphate-P concentrations appear to have decreased, for reasons not identified herein, with no clear improvement in overall ecological status. To compound the failure to meet Good Ecological Status at most sites sampled, it has been demonstrated that sewage and industrial effluent sources of alkalinity to the river can give erroneous boundary concentrations of reactive phosphorus for WFD Ecological Status classification, and in effect relax the standards.

While the sampling resolution of the EA chemical monitoring programme, particularly in the temporal dimension, frequently attracts criticism, the resulting data archived in the WIMS database, at a national level, are an important resource that can be used, with due diligence, to assess and address problems in catchment management. In the current work, the high orthophosphate-P concentrations observed in the upper R. Taw were largely due to industrial effluent from a single plant, coupled with more minor contributions from STWs, while at the catchment scale, the enhanced summer concentrations of orthophosphate-P were due to STW effluents. These point sources appeared to be the major cause of failure to meet GES under the WFD. Reductions in orthophosphate-P loads from effluents could be achieved via chemical precipitation using metal chloride, although the

618 costs may be prohibitive. In the future, the development of an EU-wide Phosphorus Circular

619 Economy to severely restrict P losses to the environment, as advocated by the European

620 Sustainable Phosphorus Platform, may drive through these mitigation measures. The

621 estimated diffuse catchment runoff concentrations of ca. 0.03 mg L^{-1} orthophosphate-P, if

622 maintained at this level, would alone cause many sites to fail GES under the WFD Phase 2

623 standards. There is no requirement under the current UWWTD to further reduce

624 orthophosphate-P loads from STW and industrial effluents in the Taw catchment and so

625 unless driven by the WFD, it is unlikely that most rivers in the Taw catchment will achieve

626 GES in the foreseeable future.

627   For catchments like the Taw, with an extensive sampling history, both spatially and

628 temporally, it is arguable that the regulatory agencies should investigate alternative sampling

629 strategies that would provide more useful data for management / policy purposes while at the

630 same time be resource neutral and still fulfil statutory monitoring obligations. For example,

631 the number of sites regularly sampled could be reduced to those with known issues plus sites

632 located at the catchment outlets, including sub-catchments, where sampling frequency could

633 be markedly increased. The latter approach would provide improved estimates of catchment

634 nutrient loads, as defined in this study, and at the same time allow more accurate and precise

635 land to sea flux estimates of contaminants required by OSPAR. Reduced routine sample

636 throughput could also allow a more comprehensive set of analyses per sample, of particular

637 importance for phosphorus because it occurs in a variety of inorganic and organic fractions

638 with varying bioavailabilities. With anticipated changes in rainfall patterns, in particular

639 increases in the frequency of short sharp summer rain events, it may be prudent to undertake

640 "smart sampling" during these events (using a combination of meteorological predictions for

641 summer rainfall with in situ measurement technologies) in order to improve understanding of

642 nutrient transfers during intermittent wetting up of catchments. The aspiration for in situ

643 measurements, inter alia, is that they should measure the bioavailable P as defined by the

644 Environmental Quality Standard that is current at the time; while in situ measurements of

645 (dissolved) reactive phosphorus in rivers are now being more frequently reported, it is evident

646 that the instrumentation requires further development, particularly in relation to the more

647 specific definition of filtered reactive phosphorus given in the WFD Phase 2 standard.

648   The contribution of sewage effluent to riverine concentrations of alkalinity appeared

649 significant in the Taw, particularly during the key summer months. Given the extent of

650 urbanisation within Europe it would appear prudent to extend this analysis in order to

651 properly assess the contributions of effluent alkalinity to river alkalinity across the EU. This

652 would no doubt provide a more nuanced derivation of river phosphorus standards in a future

653 WFD river basin management cycle.

772   Table 1. River flow gauging stations included in this study.

Gauging station	NRFA station #	% of total catchment drained	Comments	Baseflow index	Daily flow data (m³ s⁻¹)			
					Mean	Min	Max	Q_{95}
Umberleigh (Taw)	50001	68	Significant modification to flows owing to public water supply abstraction. Augmentation from the Exe catchment at low flows stopped end 2002.	0.43	18.0	0.20	364	1.23
Taw Bridge (Taw)	50007	6	Water abstractions at Taw Marsh ceased ~ 1999. Cheese factory at North Taw bridge abstracts from borehole but also compensates into river at low flow.	0.47	1.80	0.02	51.1	0.17
Woodleigh (Mole)	50006	29	Low flows moderately affected by public water supply abstraction and augmentation from Exe-Taw transfers.	0.47	8.79	0.20	143	0.87

773   Data from the National River Flow Archive (NRFA; http://www.ceh.ac.uk/data/nrfa/)

774

Table 2. Temporal trend analysis of orthophosphate-P concentrations for sites 2, 7 (2003 – 2013) and 14 (2003 – 2009).

Site (n)	Orthophosphate-P (flow adjusted concentrations)								
	r_s	Probr_s	trend	τ	Prob$_{MK}$	trend	τ	Prob$_{SK}$	trend
2 (126)	-0.32	< 0.001	↓	-0.22	< 0.001	↓	-0.35	< 0.001	↓
7 (129)	-0.42	< 0.001	↓	-0.28	< 0.001	↓	-0.32	< 0.001	↓
14 (83)	-0.37	< 0.001	↓	-0.22	< 0.001	↓	-0.30	0.007	↓

Site (n)	Orthophosphate-P (non-flow adjusted concentrations)								
	r_s	Probr_s	trend	τ	Prob$_{MK}$	trend	τ	Prob$_{SK}$	trend
2 (126)	-0.32	< 0.001	↓	-0.22	< 0.001	↓	-0.36	< 0.001	↓
7 (129)	-0.35	< 0.001	↓	-0.23	< 0.001	↓	-0.37	< 0.001	↓
14 (83)	-0.40	< 0.001	↓	-0.26	< 0.001	↓	-0.47	< 0.001	↓

n, number of data points; r_s, Spearman's Rho correlation coefficient; τ, Kendall's tau correlation coefficient; prob, p value of the significance of the trend; MK, Mann Kendall; SK, Seasonal Kendall

Box 1. Estimation of the contribution of effluents, groundwater and diffuse catchment sources to river alkalinity loads at sites 2, 7 and 14 in the Taw catchment.

Effluent and groundwater sources				
Calculations: the approach uses equations (1) – (5) given in the main text				
Component	Unit	Site 2	Site 7	Site 14
Q_{dwf_stw}[a]	$m^3 s^{-1}$	0.067	0.031	0.018
Q_{river_min}[b]	$m^3 s^{-1}$	0.692	0.103	0.399
$Q_{groundwater}$[c]	$m^3 s^{-1}$	0.625	0.072	0.381
$Alkalinity_{stw}$[d]	$g\ CaCO_3\ m^{-3}$	51.4	51.4	51.4
$Alkalinity_{groundwater}$[e]	$g\ CaCO_3\ m^{-3}$	7.1	7.1	7.1
$Alkalinity\_load_{effluent}$	$g\ s^{-1}$	3.42	1.59	0.95
$Alkalinity\_load_{groundwater}$	$g\ s^{-1}$	4.46	0.51	2.71
% Alkalinity from effluent		43.4	75.6	25.8

[a] Site 2 = Taw creamery + 13 STW; Site 7 = Taw creamery + 2 STW; Site 14 = 3 STW. Dry Weather Flow (dwf) data from the EA.
[b] Flow values are from the period coincident with the chemical data.
[c] $Q_{groundwater} = Q_{river\_min} - \Sigma Q_{dwf\_stw}$.
[d] Value from Beaford STW on the nearby R. Torridge. There are no alkalinity data for Taw STWs, but the range for South West River Basin District STWs is 14 – 444 mg $CaCO_3$ L^{-1}. Data from the EA.
[e] Median value for nearby Dartmoor groundwater (range 4.1 – 34.4 mg $CaCO_3$ L^{-1}; from [48]). No data for Taw catchment.

Diffuse catchment source
Requirement: the key requirement for this approach is that alkalinity should be conservative in the river. Using bivariate plots analogous to those given in SI 4(c) for orthophosphate-P it can be seen that alkalinity is approximately conservative, as shown in the three figures below.

Site 2	Site 7	Site 14
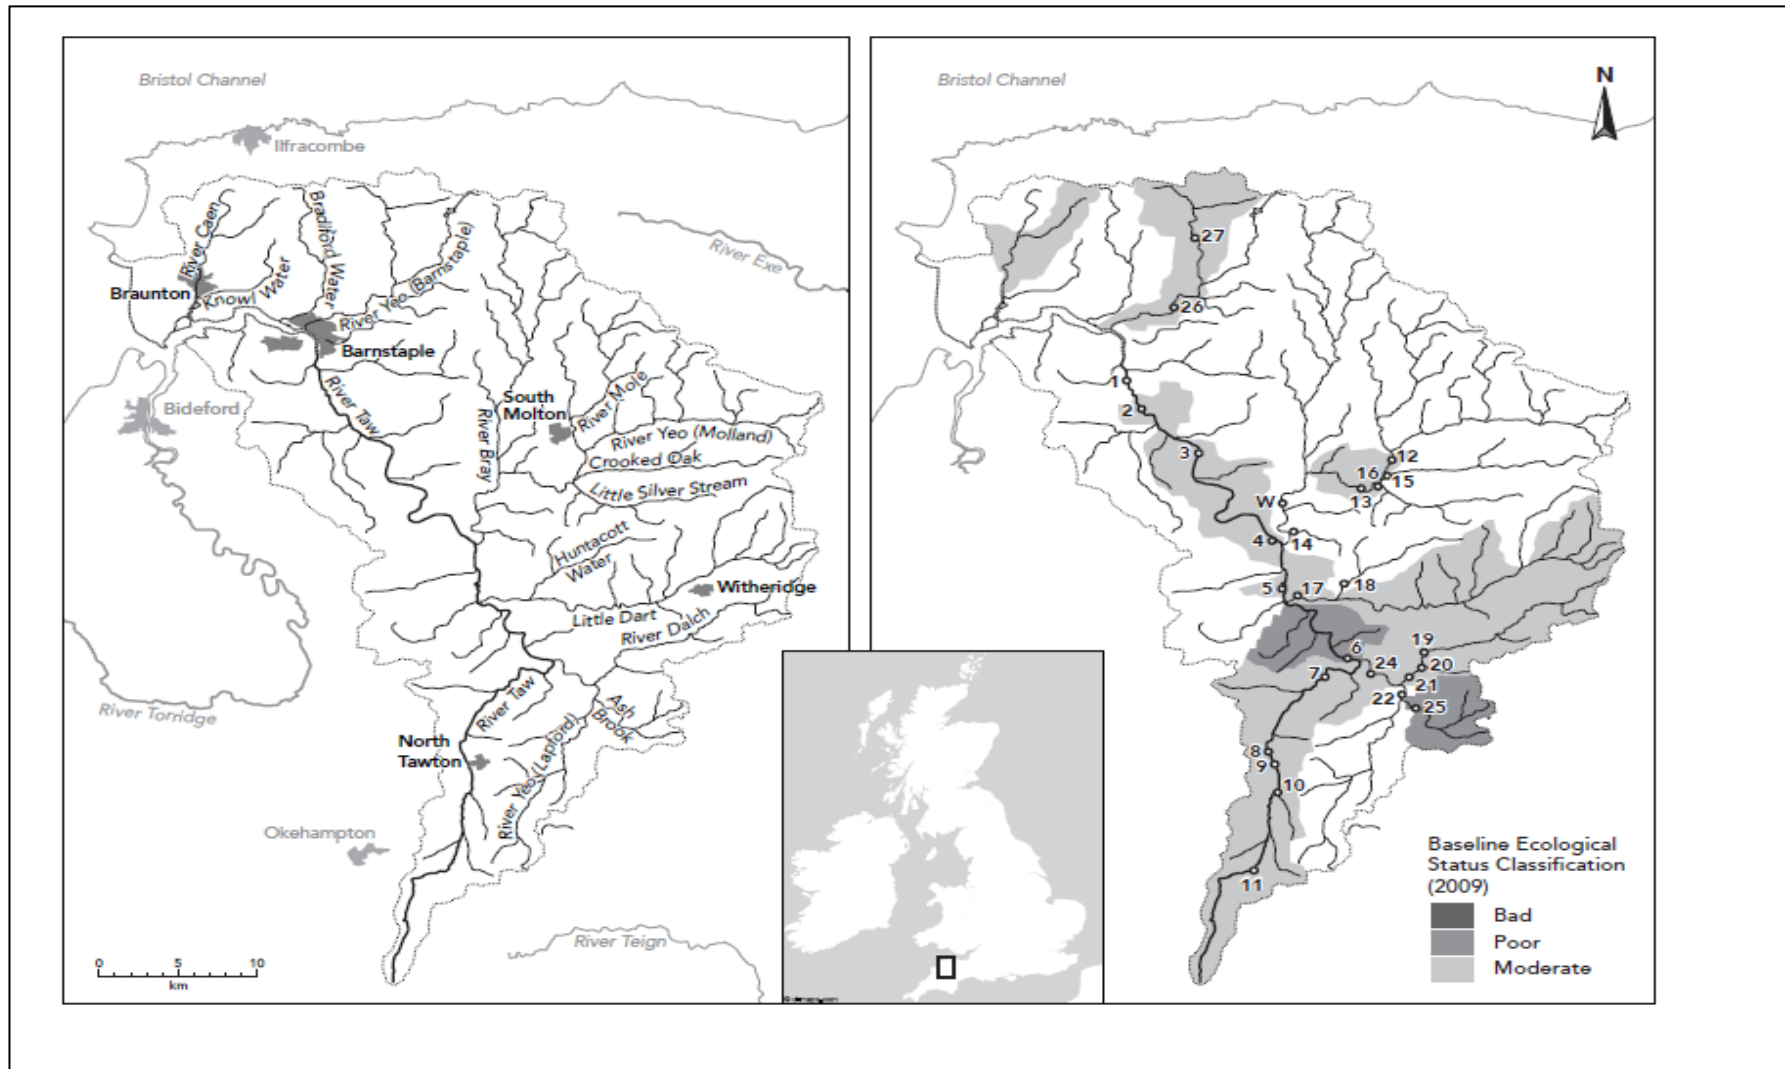

Figure 1. Left panel: place and river names; right panel: sampling sites (number) and gauging stations (U = Umberleigh, TB = Taw Bridge, W = Woodleigh). The baseline Ecological Status classification of 2009 [20] is also shown in the right panel.
**REQUIRES MINOR EDITS**

Figure 2. Estimated concentrations of orthophosphate-P in the river at site 7 (Taw Bridge), between October 2006 and March 2014, due to effluent inputs from the Taw Valley Creamery and the sewage treatment works located on the upper R. Taw. Also shown are the measured concentrations of orthophosphate-P from the EA WIMS dataset for the same period. For the estimated concentrations, orthophosphate-P loads (g P d^{-1}, derived from effluent flow and concentration data) in the effluents were diluted in to the river flow (m^3 d^{-1}) gauged for that day and conservative behaviour of orthophosphate-P assumed.
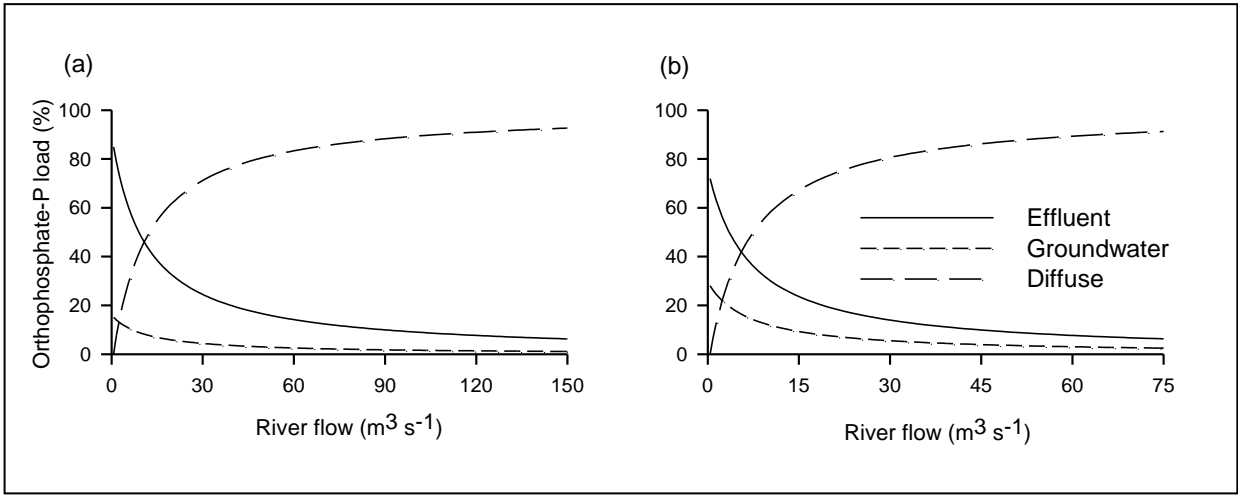

Figure 3. Calculated orthophosphate-P load from effluent, groundwater and diffuse run-off (%) vs river flow (m^3 s^{-1}) at (a) site 2 on the R. Taw and (b) site 14 on the R. Mole. Note changes in scales.
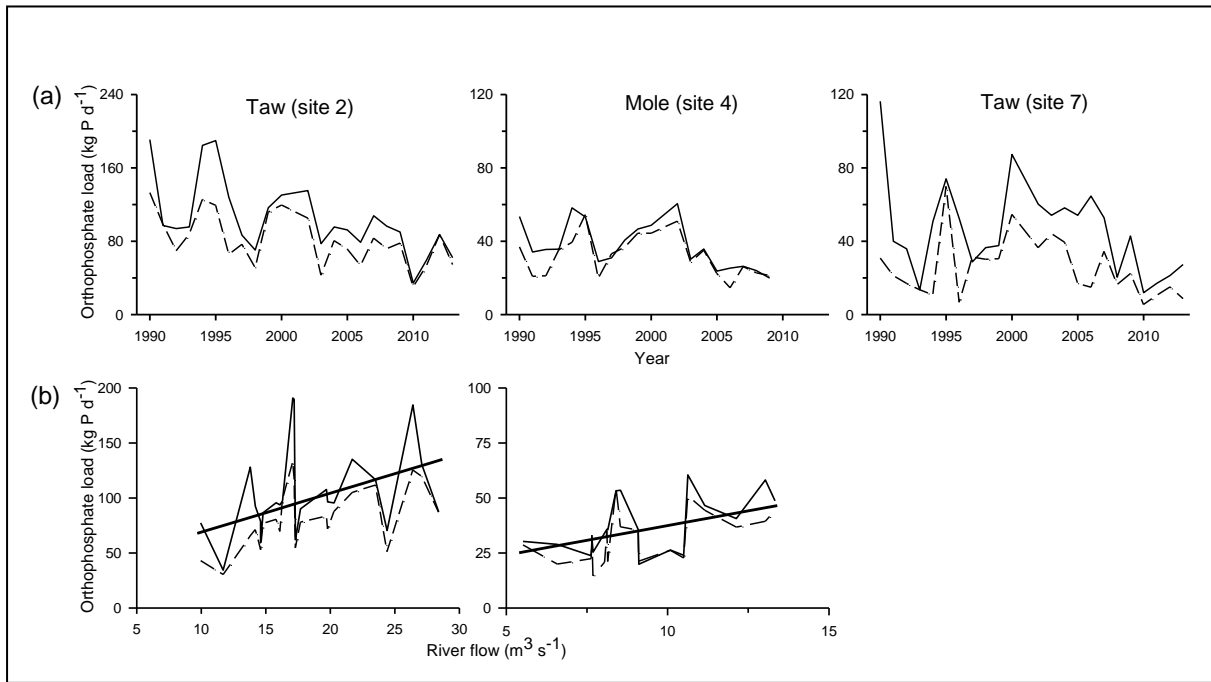

Figure 4. (a) Orthophosphate-P load (kg P d^{-1}) for each year and (b) orthophosphate-P load (kg P d^{-1}) vs annual mean flow (m^3 s^{-1}) for each year at three sites on the R. Taw and R. Mole. Note changes in scales. Thin solid line, Method 5 mean value; dashed line, Method 5 median value; thick solid line, source apportionment model value.
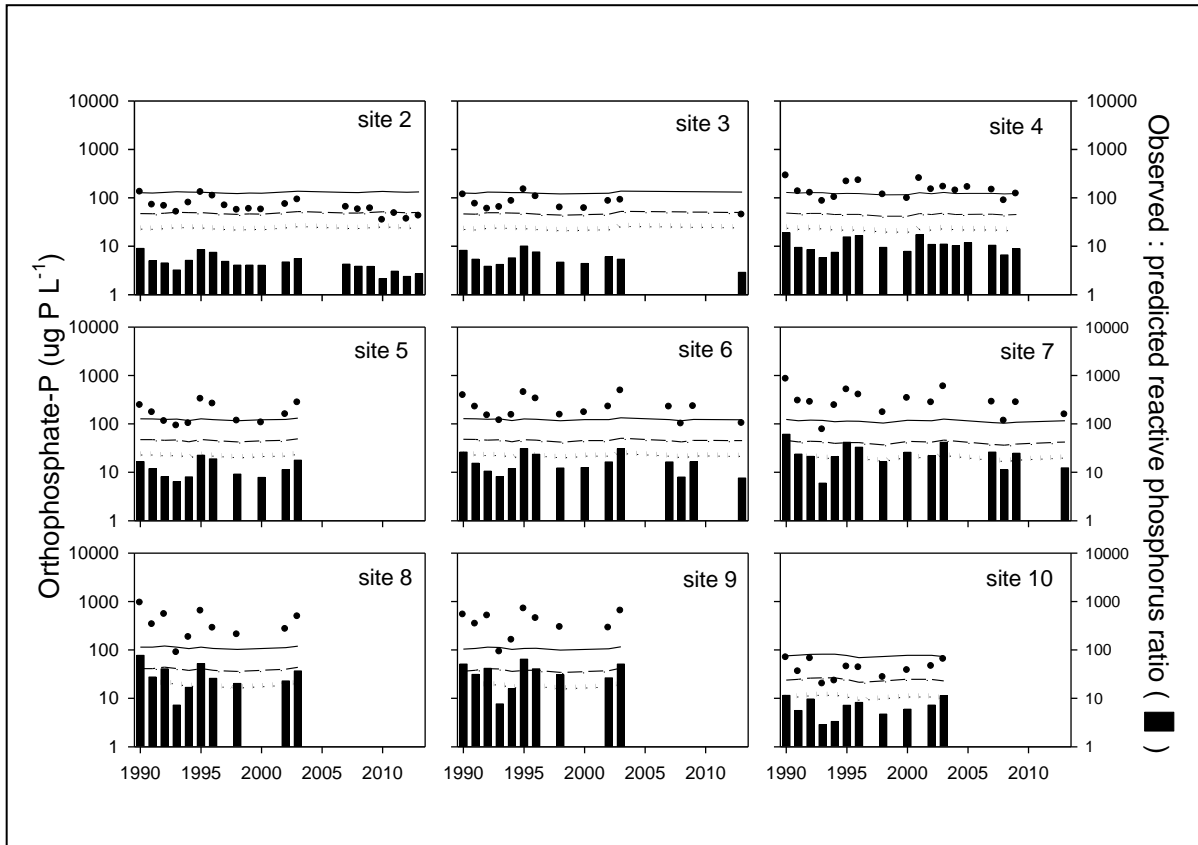

Figure 5. Water Framework Directive (phase 2) reactive phosphorus standards for the R. Taw. Solid line, poor/moderate boundary; dashed line, moderate/good boundary; dotted line, good/high boundary (all µg P L^{-1}). Observed mean annual concentrations of orthophosphate-P (●; µg P L^{-1}). Vertical bars show the ratio of the observed and predicted reactive phosphorus concentrations.
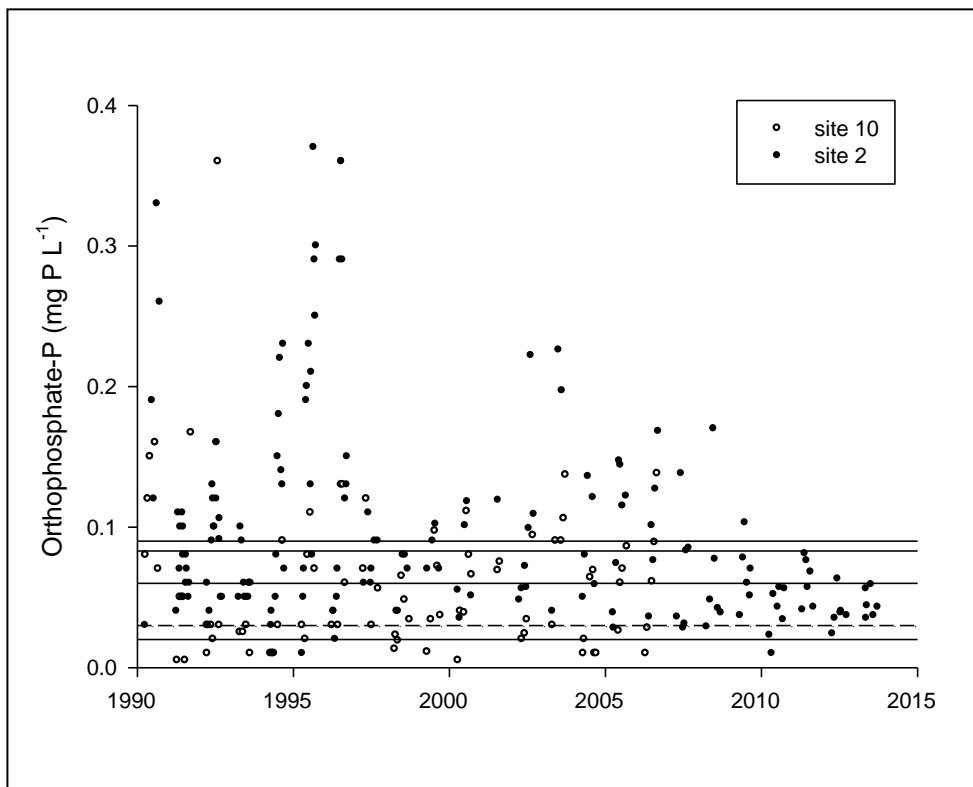

Figure 6. Orthophosphate-P (mg P L^{-1}) concentrations at site 10 and site 2 on the R. Taw during the April to September algal growing period. The horizontal lines show the Phosphorus Limiting Concentrations (PLC), reported for different UK and US rivers, below which P was the limiting nutrient and periphyton growth declined. The dashed line shows the concentration below which a positive change in diatom community composition was observed. See Bowes et al.[54] for a more detailed account of the PLC data.
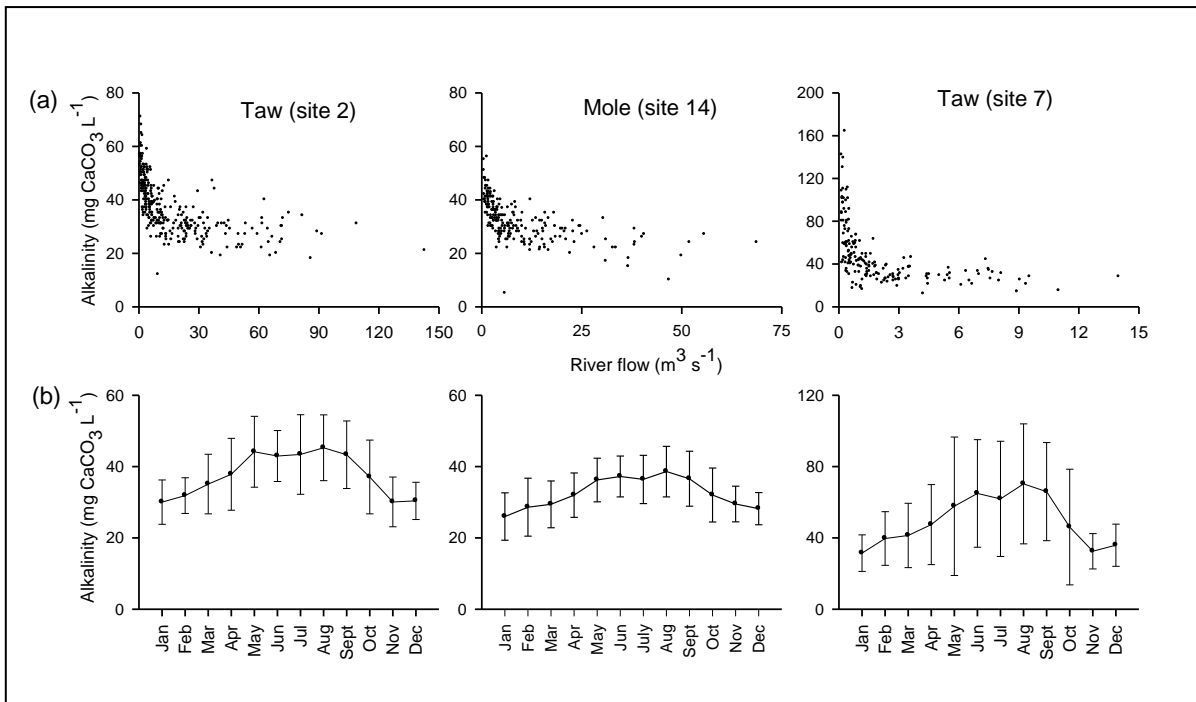

Figure 7. (a) Concentrations of total alkalinity (mg $CaCO_3$ L^{-1}) vs river flow (m^3 s^{-1}) for all years at gauged sites on the R. Taw and R. Mole. (b) Monthly mean ($\pm$ 1 standard deviation) concentrations of total alkalinity (mg $CaCO_3$ L^{-1}) for the same sites. Note changes in concentration scales.
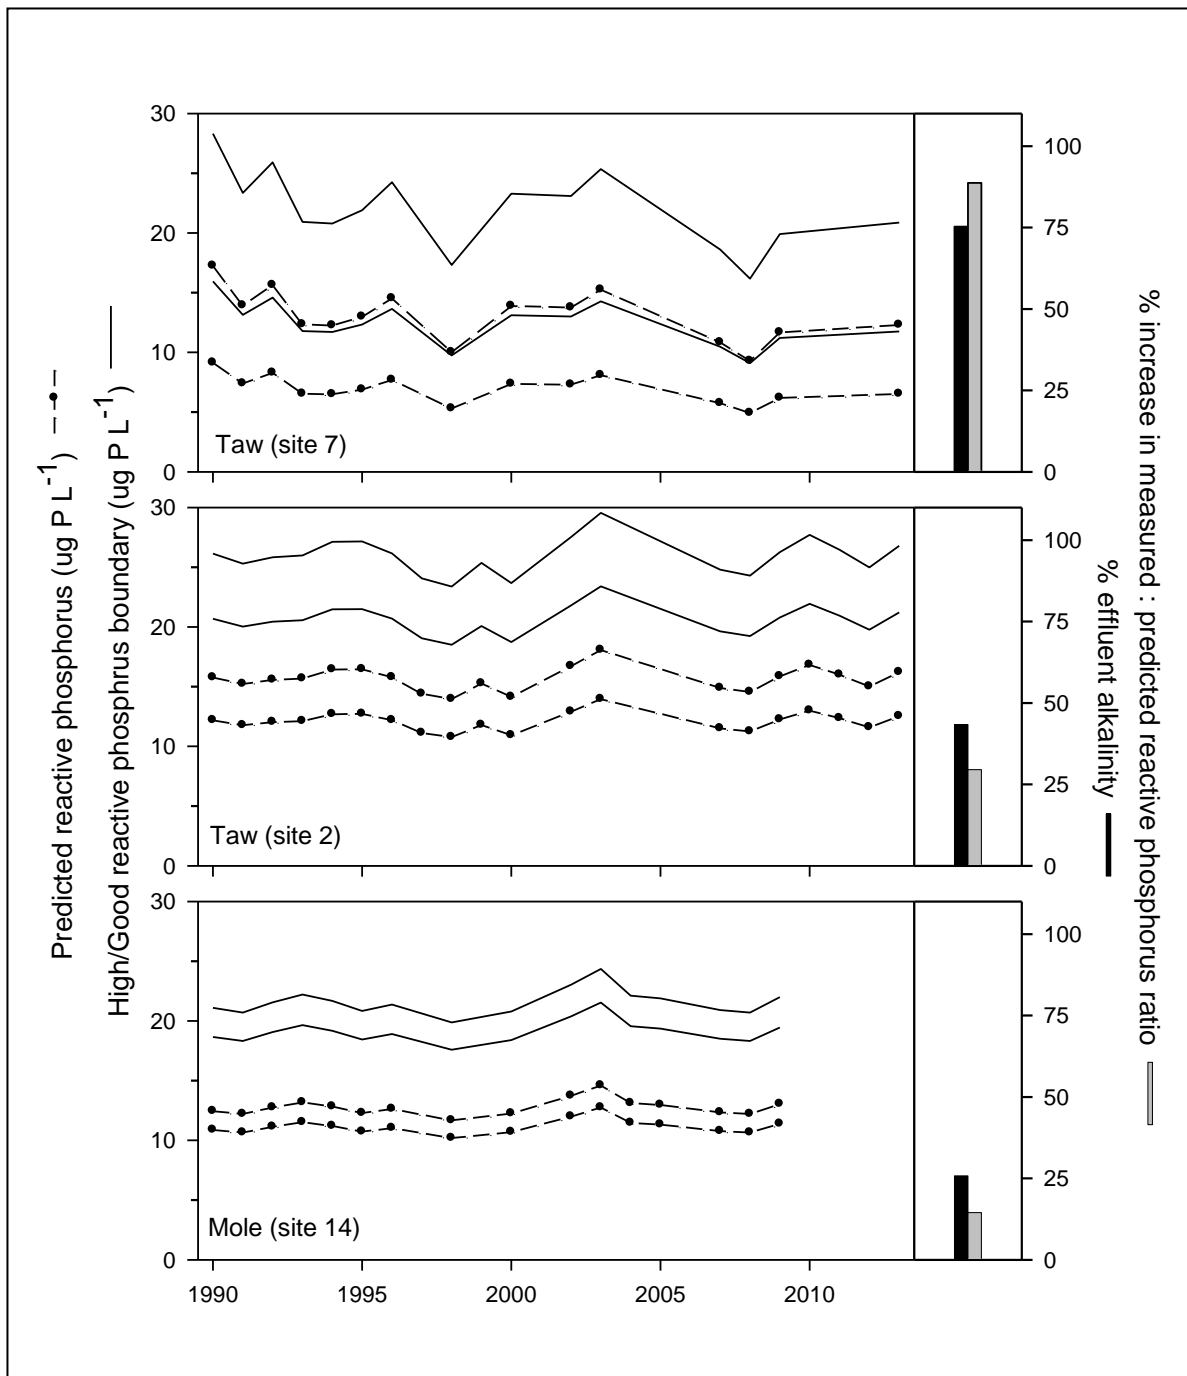

Figure 8. Right panel: Bar chart shows the % contribution of effluent to the measured river alkalinity at each site and the % increase in the measured : predicted reactive phosphorus (RP) ratio after subtraction of the effluent component of the measured alkalinity. Left panel: Solid lines show the decrease in the High/Good boundary concentration of RP, while the circle/dashed lines show the decrease in the predicted RP concentration, after subtraction of the effluent component of the measured alkalinity. Analysis for the summer period (April – September) only.
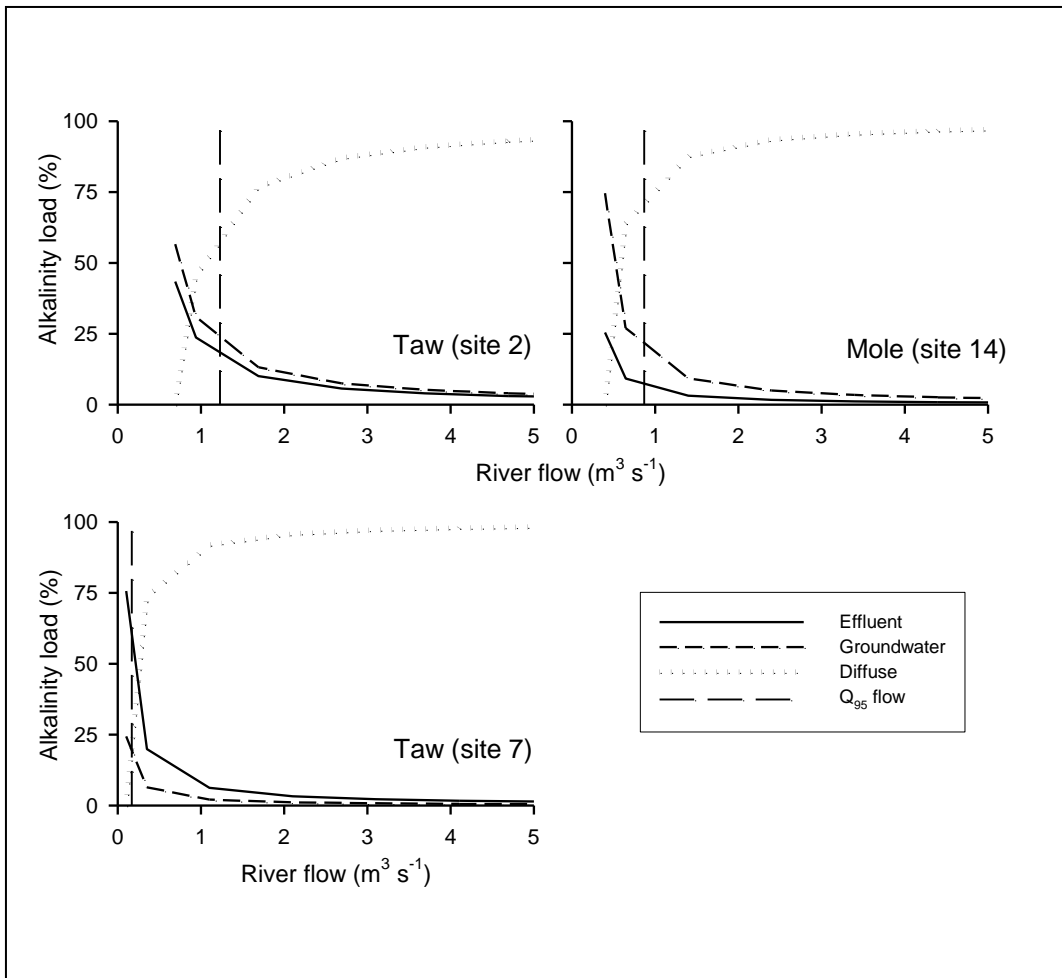

Figure 9. Estimated contribution to river alkalinity load from effluent, groundwater and diffuse run-off (%) *vs* river flow (m^3 s^{-1}) at three sites on the R. Taw and R. Mole. The Q_{95} flow values are from Table 1.

Supplementary Information 1. Sampling site, data availability, location and altitude.

[a] Altitudes from gridreferencefinder.com. d/s, downstream; u/s, upstream
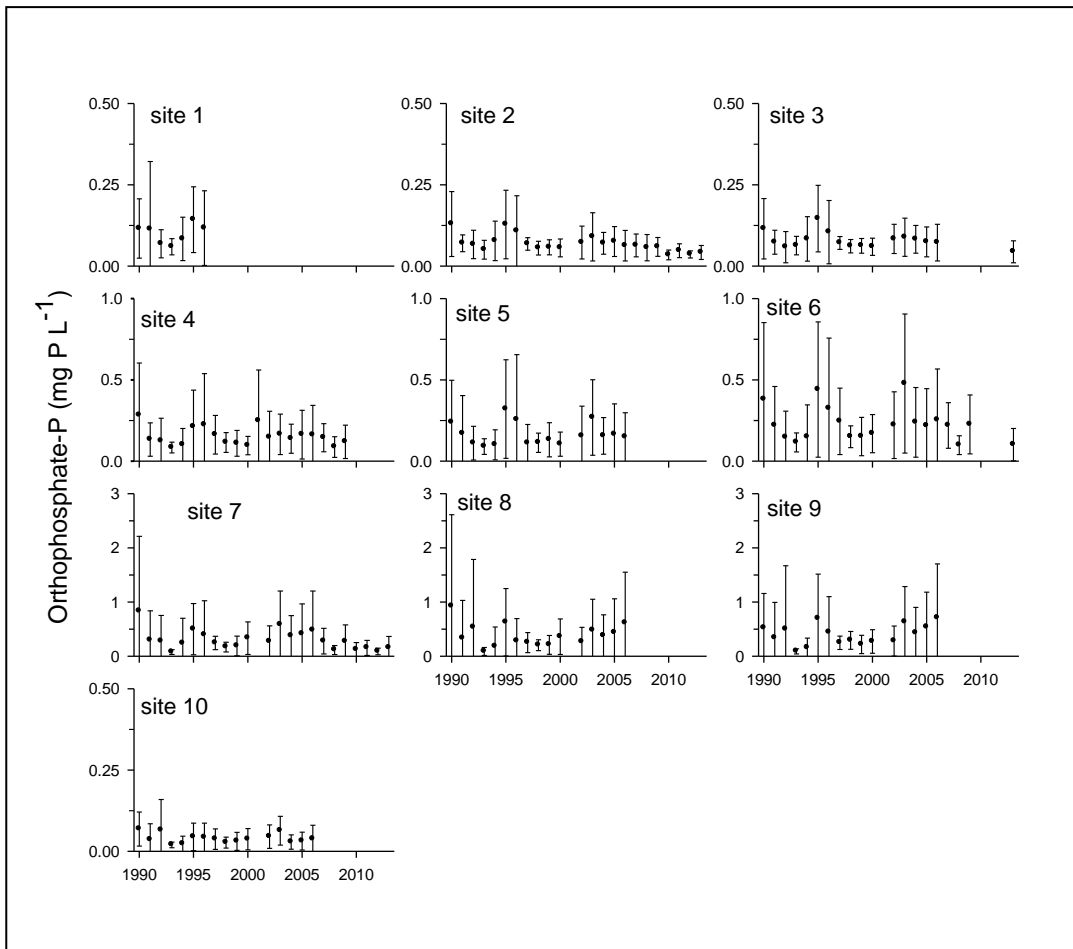

Supplementary Information 2. Annual mean (± 1 standard deviation) concentrations of orthophosphate-P (mg P L^{-1}) in the R. Taw (site locations are shown in Fig. 1). Note changes in concentration scales. Concentrations at site 11 were generally less than the limit of detection (0.04 mg P L^{-1}) and are not included.
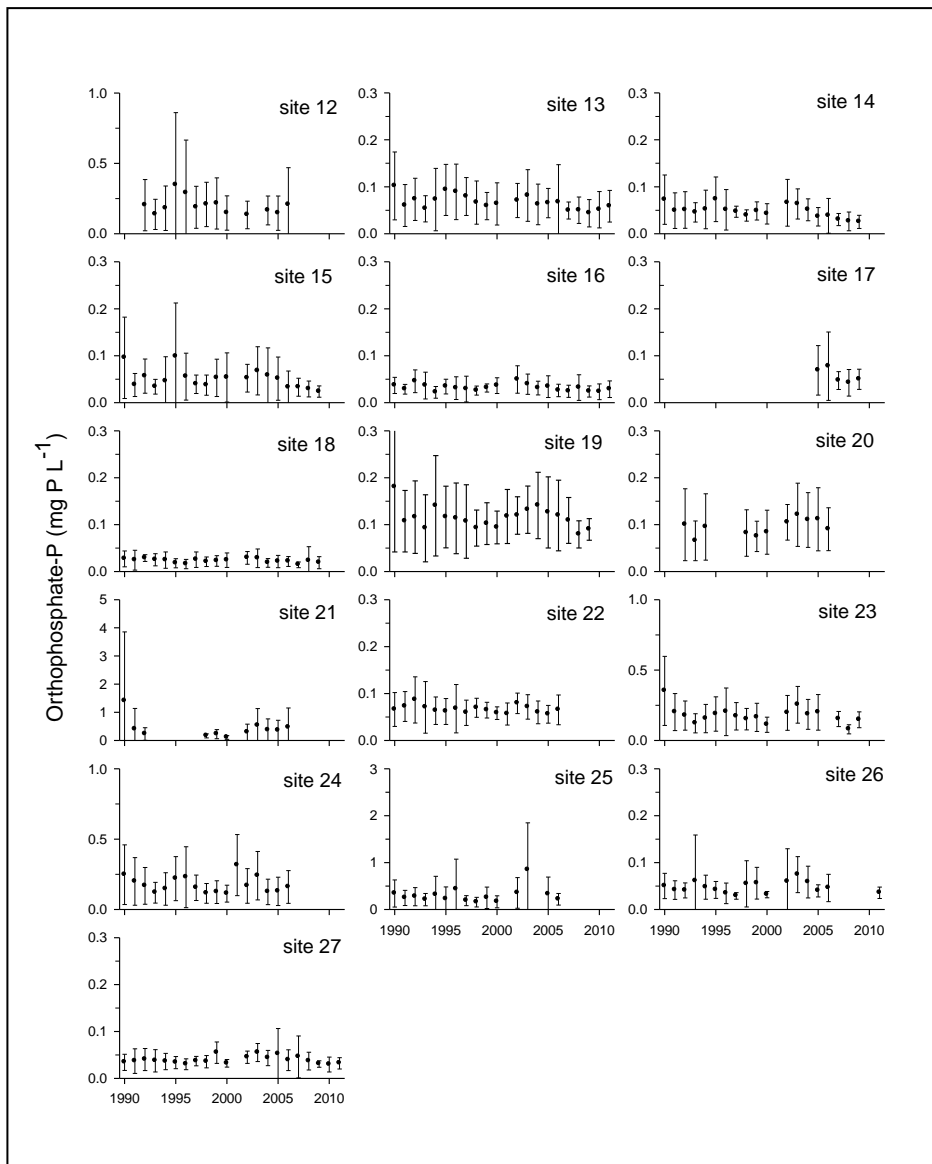

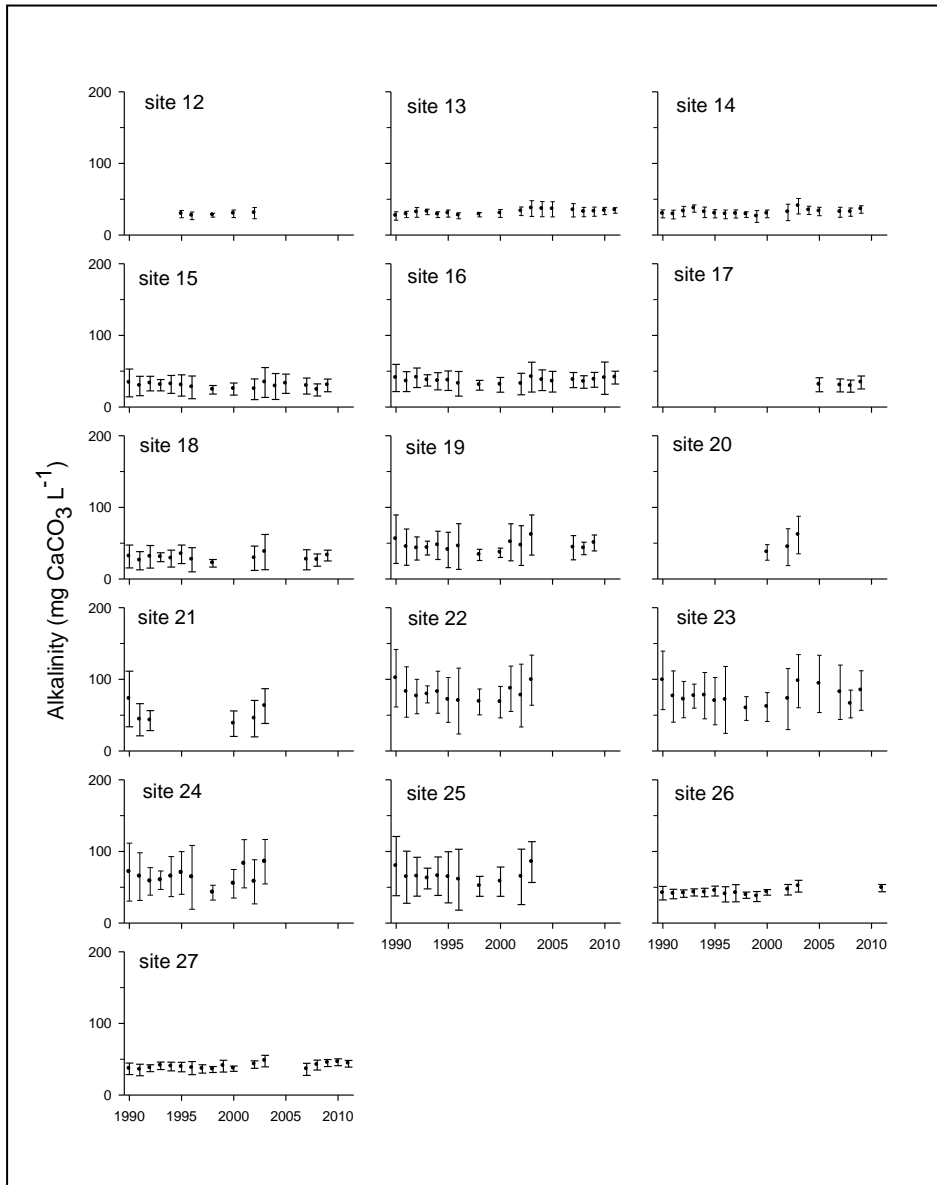

Supplementary Information 3. Annual mean (± 1 standard deviation) concentrations of orthophosphate-P (mg P L^{-1}) in the Taw tributary rivers (site locations are shown in Fig. 1). Note changes in concentration scales.
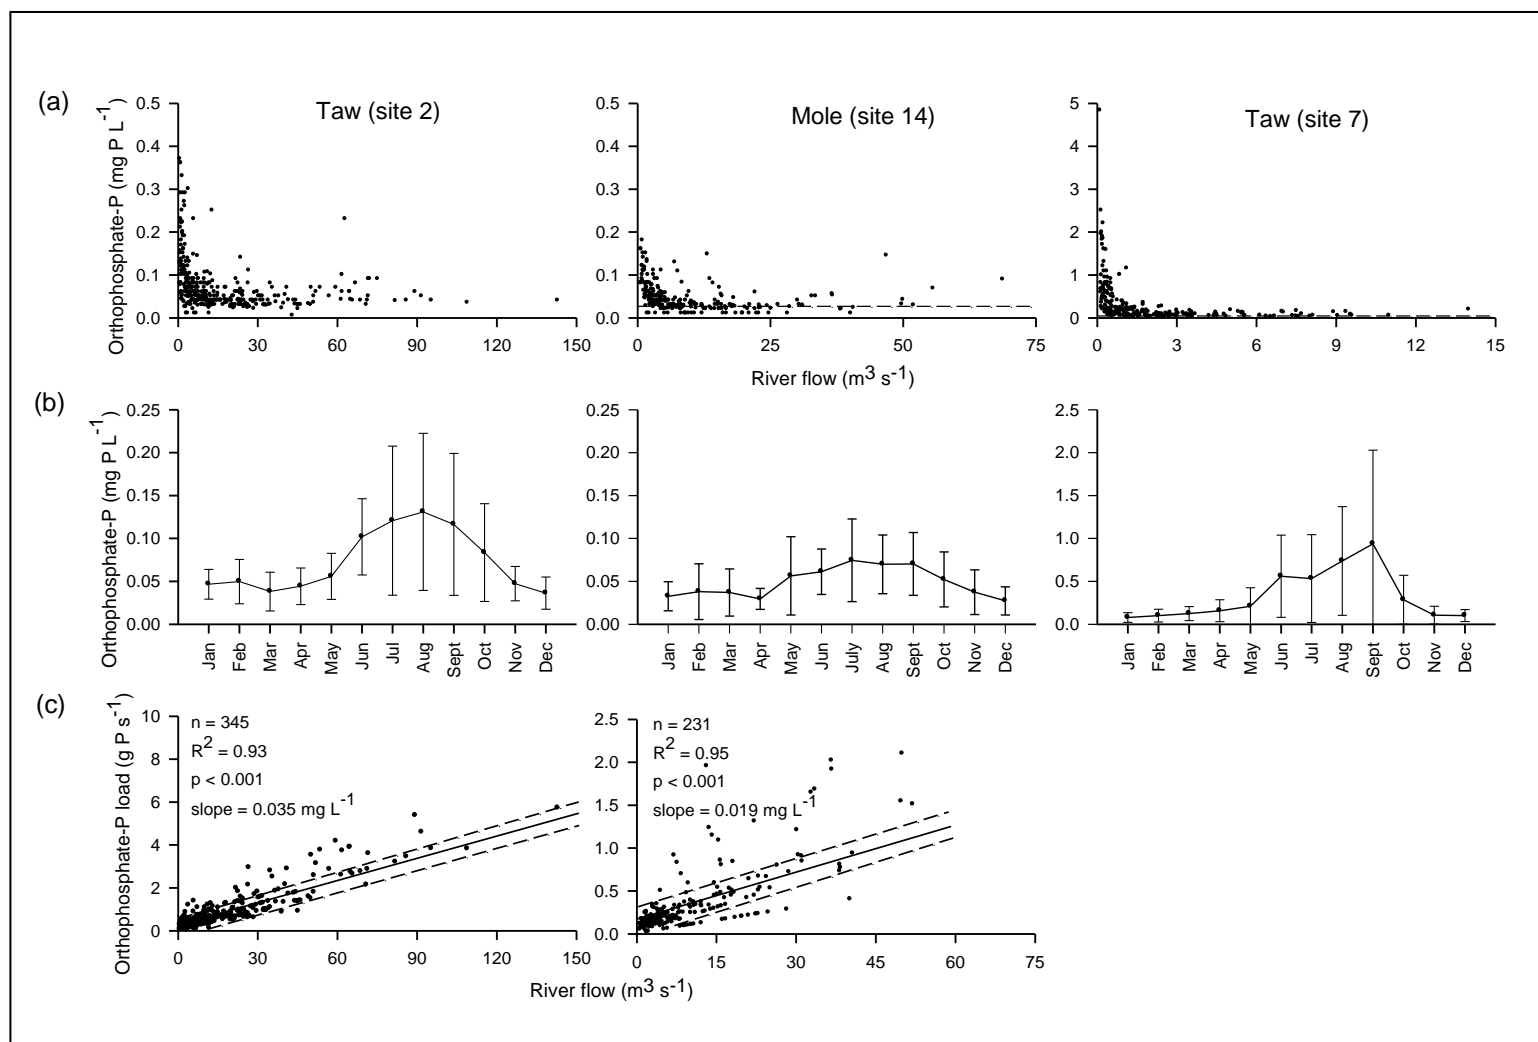

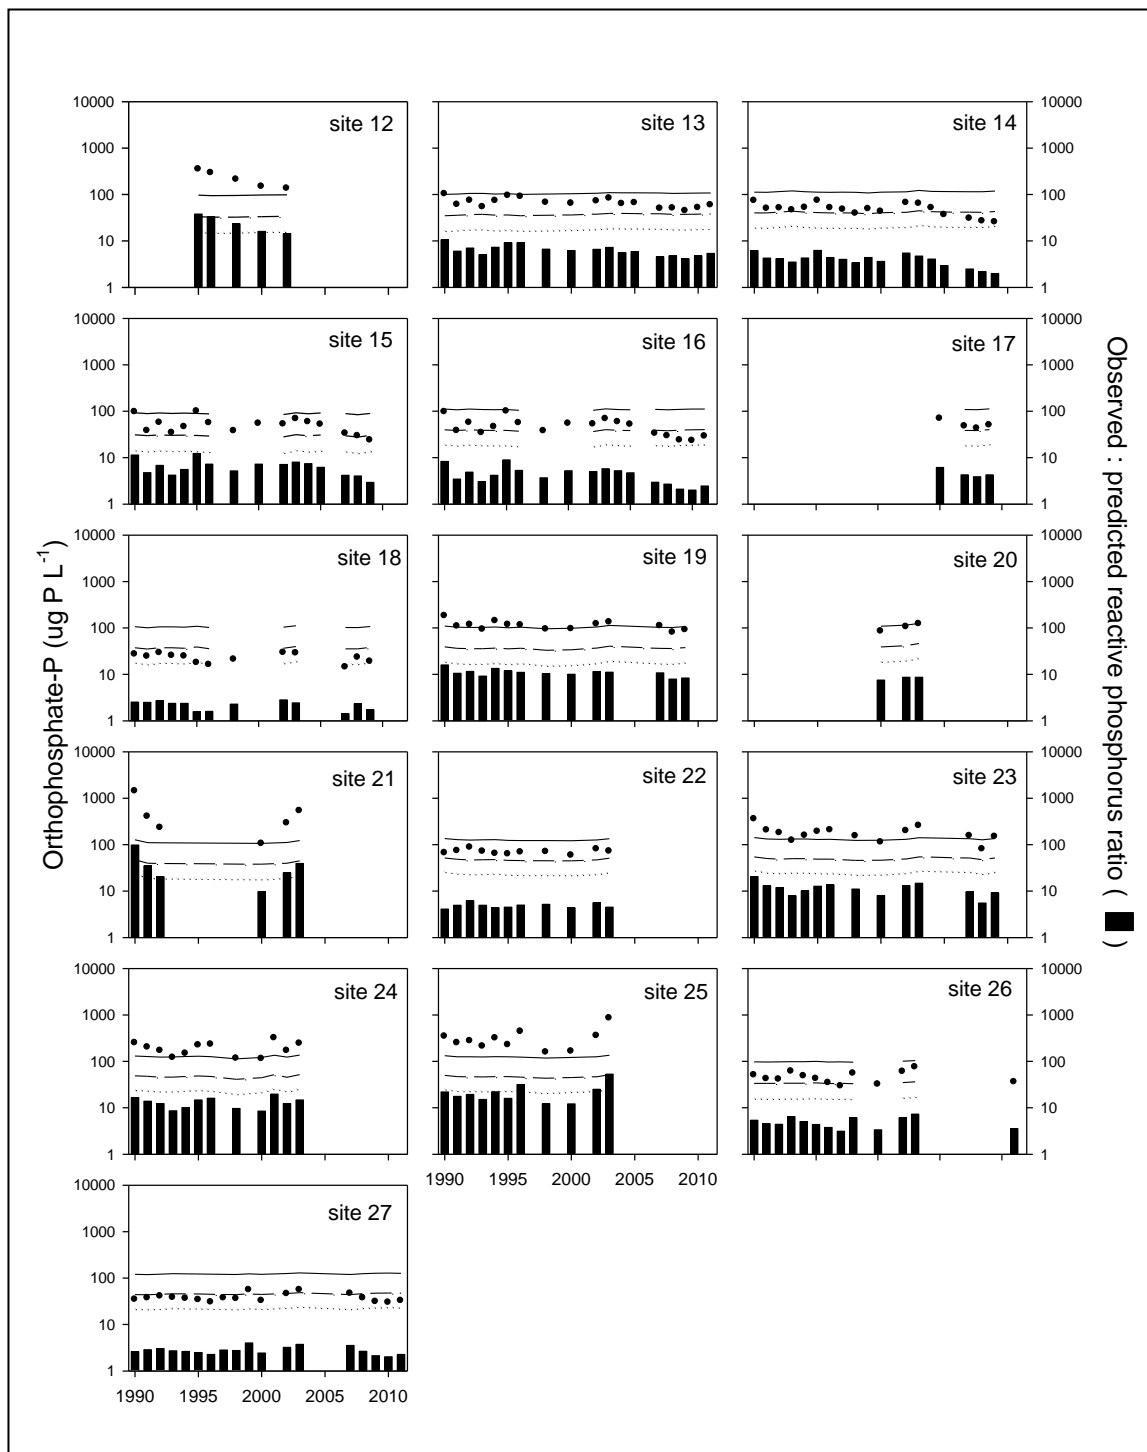

Supplementary Information 4. (a) Concentrations of orthophosphate-P (mg P L^{-1}) *vs* river flow (m^3 s^{-1}) for all years (1990 – 2013) at gauged sites on the R. Taw and R. Mole (site locations are shown in Fig. 1). (b) Monthly mean (± 1 standard deviation) concentrations of orthophosphate-P (mg P L^{-1}) for the same sites. (c) Orthophosphate-P load (g P s^{-1}) *vs* river flow (m^3 s^{-1}) for all years for the sites representing the outlets of the two rivers. Solid and dashed lines are the bisquare weight linear regression best fit and 95 % CI, respectively. Note changes in scales.
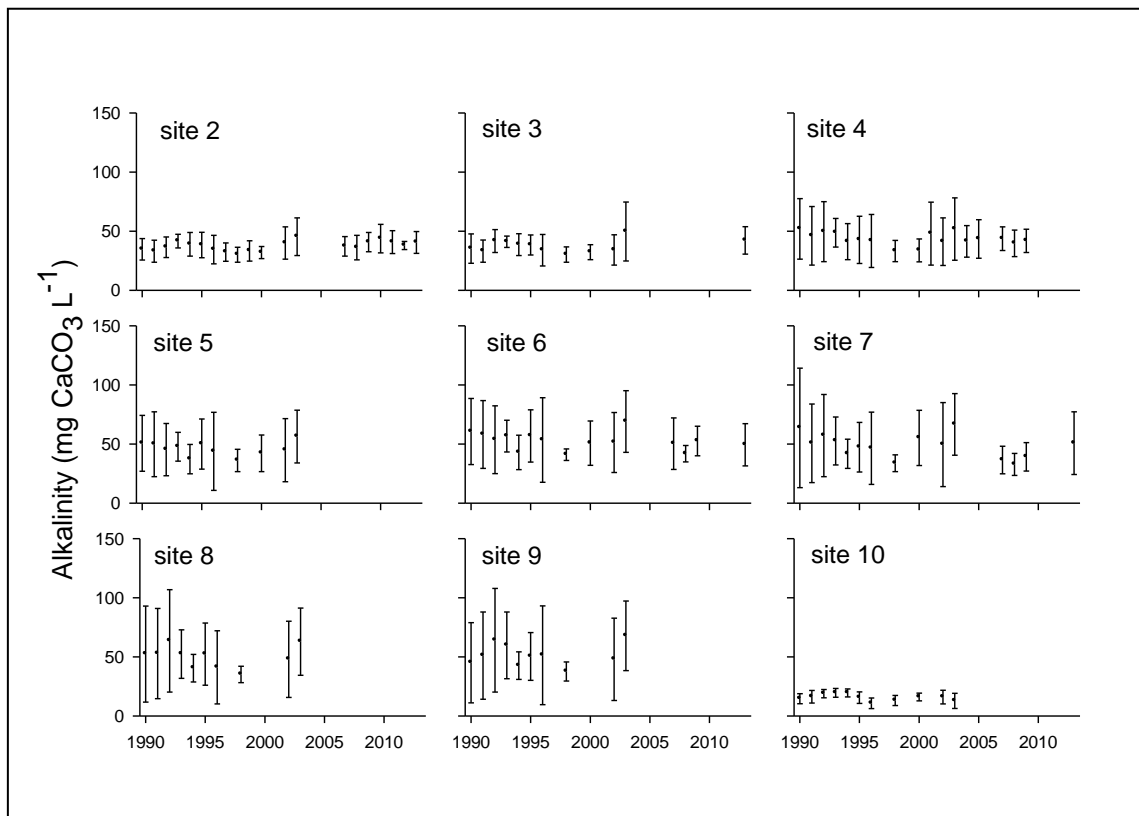

Supplementary Information 5. Annual mean (± 1 standard deviation) concentrations of total alkalinity (mg CaCO$_3$ L^{-1}) in the R. Taw (site locations are shown in Fig. 1)

Supplementary Information 6. Annual mean (± 1 standard deviation) concentrations of total alkalinity (mg CaCO$_3$ L^{-1}) in Taw tributary rivers (site locations are shown in Fig. 1).

Supplementary Information 7. Water Framework Directive (phase 2) reactive phosphorus standards for Taw tributary rivers. Solid line, poor/moderate boundary; dashed line, moderate/good boundary; dotted line, good/high boundary (all µg P L^{-1}). Mean annual concentrations of orthophosphate-P (●; µg P L^{-1}). Vertical bars show the ratio of the observed and predicted reactive phosphorus concentrations. Site locations are shown in Fig. 1.
