40 ABSTRACT

41 The eastern Sahara Desert is one of the most climatically sensitive areas on Earth, varying from 42 lake-studded savanna woodland to hyper-arid desert over the course of a glacial-interglacial 43 cycle. In presently arid Sudan there is widespread evidence that a very large freshwater lake once 44 filled the White Nile River valley. Here we present the first quantitative estimate for the 45 dimensions of the lake and a direct age for the emplacement of one of the shorelines. Using a profile dating approach with the cosmogenic nuclide 10 Be, we estimate an exposure age of 109 ± 46 47 8 ka for this megalake, indicating it formed during the last interglacial period. This age is 48 supported by optically stimulated luminescence dating of Blue Nile palaeochannels associated 49 with the lake. Using a high-resolution digital elevation model we estimate that the lake was more than 45,000 km² in area, making it comparable to the largest freshwater lakes on Earth today. We 50 51 attribute the lake's existence to seasonal flood pulses as a result of local damming of the White 52 Nile by a more southerly position of the Blue Nile and greatly increased precipitation associated 53 with a super monsoon.

54

56 **INTRODUCTION**

The Nile is the longest river in the world and its basin extends over ~ 3 million km² 57 (Figure 1a). Geomorphic records show that the flow of the White Nile has varied dramatically 58 through time as a result of climate change (Williams et al., 2010). These changes in flow have 59 60 had a profound impact on the environment and the habitability of the lower basin. Since at least 61 the middle Pleistocene the Nile has acted as a corridor for human dispersal and a refuge during periods of aridity (Basell, 2008). The occurrence of warmer, wetter conditions after the last 62 glacial maximum (Gasse, 2000) coincides with the advent of Neolithic farming in the Nile vallev 63 64 and the emergence of one of the world's great urban civilizations in Egypt (Kuper and Kröpelin, 65 2006).

66 Sudan was much wetter in the early Holocene than at present, with lakes in the Sahara Desert between ~9500 and 4500 ¹⁴C yr BP (Hoelzmann et al., 2000). At this time the Nile 67 flooded up to 5 m above modern river levels forming a lake 20-40 km wide (Williams et al., 68 69 2006). Above the Holocene flood level, the presence of a prominent shoreline led Williams et al. 70 (2003) to propose the presence of an even larger lake. In order to maintain a large lake in Sudan, 71 major shifts in regional atmospheric circulation are required (Williams et al., 2003). Attempts 72 have been made to date this White Nile megalake. However, the age remains ambiguous, with 73 estimates ranging from the Holocene back to 400 ka (Williams et al., 2003; Williams et al., 74 2010).

EXPOSURE DATING AND OPTICALLY STIMULATED LUMINESCENCE 75

76 Given the possible maximum age of the shoreline, we chose to exposure date deposition of the shoreline using the cosmogenic nuclide ¹⁰Be, which can provide age constraints beyond 77 78 the limits of radiocarbon and luminescence techniques. Samples for dating were collected from a 79 shoreline on a well-preserved cuspate foreland near Jebelein in south-central Sudan (Site A Fig. 80 1B; Supplemental Table S1). The shoreline lies ~20 m above the modern Nile River at ~400 m at 81 12.6 °N. An original survey used the old Alexandria datum and gave an elevation of 386 m for 82 the break in slope at the edge of the shoreline (Williams et al., 2003). The gravel and coarse sand 83 constituting the shoreline is locally derived from weathering of granite inselbergs adjacent to the 84 Nile River, subsequently transported by longshore drift. Wave action has worked the weathered 85 gravel, which is highly rounded (Fig. 2). The shoreline has a typical width of 600 m and only 86 extends about 10 km to the north and south of the inselbergs. We also sampled the summit of the nearest inselberg, Jebel Hawaja, to estimate likely ¹⁰Be inheritance in the gravel. 87

88 To associate the shoreline formation with contemporary channel development along the 89 Nile, we applied optically stimulated luminescence at three sites further north. A series of former 90 Blue Nile channels radiate northwest across the alluvial plain west of the Blue Nile towards the 91 White Nile and coincide with the northern limit of the lake (Williams, 2009) (Fig. 1B). The first 92 site dated (Site B) is located on a palaeochannel on the east bank of the White Nile. Site C is on 93 the clay floodplain of another channel between a large north-south aligned sand dune and the 94 White Nile. This channel can be traced laterally northwest on aerial photographs until it runs 95 beneath the linear dune on its path towards the White Nile. The site B sands may be part of this 96 same channel complex. Site D is located on the east bank of the current Blue Nile Channel above 97 its current level (Fig. 3).

98 **RESULTS**

99 The ¹⁰Be concentration in the depth profile decreases with depth as expected (Fig. 2; 100 Table S2). The exception is the surface sample, which has a lower ¹⁰Be concentration than 101 expected because of bioturbation, and the resultant curve fit is poor ($\chi^2/\nu = 2.7$). Excluding the surface sample greatly improves the quality of the fit and the uncertainties are consistent with the curve fit ($\chi^2/\nu = 0.76$). The best-fit age is 109 ± 8 ka. The quality of the fit indicates minimal removal from or addition of sediment to the profile through time.

105 Under the assumption of steady state erosion, the three analyses from Jebel Hawaja 106 indicate that it is lowering at a rate of 1-5 m/Ma (Table 2), typical of desert inselbergs (e.g. 107 (Bierman and Caffee, 2002)). The range in these values is likely to be due to the varying degrees 108 of exfoliation observed across the summit. Sediment derived from this surface is therefore likely to have a significant ¹⁰Be inheritance. The ¹⁰Be concentrations represent a maximum for 109 110 sediment being generated from the inselberg; the steep, shielded, higher surface area flanks will contain lower concentrations of ¹⁰Be. The inherited component from the curve fit in the section is 111 112 303,500 atoms/g, consistent with weathering from the Jebel once the steep shielded flanks are 113 taken into account.

The OSL ages on channel sands at site B indicate a prolonged phase of fluvial sand entrainment and deposition in this area between about 100 and 70 ka ago (Fig. 3; Table S3). At site C the floodplain clays were deposited in the late Pleistocene and early Holocene after the resumption of the African Monsoon (Williams et al., 2006). The underlying well-sorted fluvial sand was deposited during the last interglacial period at the same time as the sand at the base of Site B. Site D has an age similar to the base of the other two sections and indicates high-energy flow at 104 ka at the site of the modern Blue Nile Channel.

Based on SRTM90 data, the White Nile Megalake at its maximum level would have extended as far north as 15° N with a length of 650 km, a maximum width of 80 km, an average depth of 6 m, and an area of 45,000 km² (see also supplemental methods). This lake area is likely to be a minimum because of progradation by the extensive Khor Abu Habl alluvial fan and encroachment of the linear dunes of the Sahara Desert formed before and during the last glacial maximum, both of which have partially blocked the valley. The maximum depth above the Holocene floodplain in the middle of the lake is ~12 m, which does not take into account Holocene sedimentation. The lake extends 150 km further south than proposed by Williams et al. (2003) and the volume would have been ~270 km³, which is more than twice the amount previously estimated by Williams et al. (2003).

131 **DISCUSSION**

132 The age of the White Nile Megalake shoreline dates the origin of the White Nile River 133 back to at least the last interglacial period. The reconstructed dimensions of the 'lake' would 134 make the White Nile at that time the widest river on Earth, and would currently rank it one of the 135 four largest lakes by area. The presence of a significant shoreline only on the eastern side of the 136 White Nile suggests that the lake was only full during the summer months of the monsoon when 137 southwesterly winds delivered rain from inner Africa and there was much greater flow into the 138 White Nile from the Ugandan lakes. The optical ages indicate at least two channels of the Blue 139 Nile were active at the same time, delivering large volumes of discharge.

140 The setting for such a large lake occupying a broad and shallow river valley without an 141 obvious dam is highly unusual on Earth today. The lack of a prominent shoreline north of Esh 142 Shawal (13° 30' N) corresponds to three important morphological features which could 143 contribute to the damming of a lake. First, the major linear dune field from the west impinges on 144 the river from ~13-14° N (Figure 1b) and was probably present in some form before the last 145 glacial maximum. This sheet of sand partially fills the eastern side of the valley and forces the 146 White Nile up against the Managil Ridge. Second, the White Nile valley narrows north of 14° N, 147 which acts to constrict the flow of the river. Third, the Blue Nile joins the White Nile at 15° 36'

N. When the unregulated Blue Nile was in flood in modern times, the flood pulse of the Blue Nile resulted in damming of the White Nile for 300 km up the valley to create a lake up to 3 km wide near its northern end (Willcocks, 1904). With completion in 1935 of the Jebel Aulia dam (Fig. 1b) on the White Nile 35 km upstream of Khartoum, the reservoir when full also produces a body of slack water that extends ~300 km upstream.

153 Our dating of the Blue Nile palaeochannels indicates that the third factor was much more 154 significant during the last interglacial period than at present. A major late Pleistocene 155 palaeochannel of the Blue Nile joined the White Nile near Naima and El Geteina (Fig. 1b), 120 156 km and 80 km south of the modern confluence, respectively (Williams, 2009) and our dating 157 demonstrates that the channel development and flooding were contemporaneous. Given 158 enhanced flow from both the Blue and the White Nile at this time, it is likely that the Blue Nile 159 floods could have acted to dam the White Nile to an elevation of 400 m. Much higher flow than 160 present is suggested by the age at Site D, indicating a distributary was also active (probably 161 during peak flooding) at this time near the site of the present Blue Nile.

The climate must have been significantly more humid during the last interglacial period 162 163 in order for such a large lake to persist in the White Nile valley. Sudan is presently arid, with 164 mean annual rainfall decreasing northwards from 780 mm at Malakal in the south to 140 mm at 165 Khartoum (Hijmans et al., 2005), reflecting limited transport of moisture northward during the 166 modern southwest monsoon. Pan evaporation rates increase northwards from 2000 mm/yr at 167 Malakal to nearly 4000 mm/yr at Khartoum (Shahin, 1985). Modern evaporation rates on a lake of 45,000 km² would amount to a total of 63,-95,000 km³/yr on a lake with a volume of only 270 168 km^3 . Modern day flow is only ~27 km^3/yr at the southern end of the lake (Williams et al., 2003) 169 and modern precipitation on the lake would be ~ 21 km³/yr, indicating that it would not be 170

171 possible to form the lake under conditions similar to the present. Ignoring lake outflow, flow 172 would need to triple or have a major contribution from the Blue Nile flood pulse, and on-lake 173 precipitation increase by 50% just to start filling the lake, provided increased cloudiness and 174 humidity led to a concomitant drop in evaporation to levels characteristic of the humid south of 175 Sudan.

176 The presence of a White Nile Megalake adds to an emerging picture that during the last 177 interglacial period the Sahara Desert was an oasis-studded savanna hosting Middle Paleolithic 178 hunter-gatherers (Wendorf et al., 1993). Identifying large lakes present during this period has 179 been hampered by difficulties in dating (Geyh and Thiedig, 2008). (Armitage et al., 2007) have 180 determined a possible high lake phase in the middle of the last interglacial period at 100 - 110 ka 181 for Lake Megafazzan in the Libyan Desert based on OSL ages from coquinas. A slightly later 182 age of 95ka has been suggested as representing a humid phase in the western Sahara Desert, 183 based on uranium-series dating of lake sediments (Causse et al., 1988). Deep sea cores taken off 184 the west coast of Africa show that during the last interglacial period the climate was more humid 185 in North Africa because there were low inputs from dust (Moreno et al., 2001) and high river 186 flow (Weldeab et al., 2007).

Further confirmation of high fluvial flow comes from deep sea cores collected from the floor of the eastern Mediterranean which show a repetitive sequence of alternating calcareous muds with a significant content of Saharan wind-blown dust, and dark organic-rich sediments, termed sapropels (Ducassou et al., 2008; Larrasoaña et al., 2003). These sapropel units are thought to have accumulated during times of enhanced freshwater inflow from the Nile and now inactive Saharan rivers (Osborne et al., 2008; Scrivner et al., 2004; Wehausen and Brumsack, 1998). The White Nile Megalake probably formed during Sapropel Unit 5 (S5) (Kroon et al., 194 1998; Lourens et al., 1996). Based on these sapropel units, (Rohling et al., 2002) have suggested 195 that the Intertropical Convergence Zone (ITCZ) penetrated seasonally approximately 21°N 196 during the last interglacial period. Global Circulation Models (GCMs) support this finding 197 (Kutzbach and Liu, 1997). The Indian Ocean monsoonal rainfall reached as far north as northern 198 Sudan during the Holocene pluvial phase (Rodrigues et al., 2000), which is thought to have been 199 of lesser magnitude than during the last interglacial (de Noblet et al., 1996).

200 The only feasible way to maintain a lake the size of the White Nile Megalake in south-201 central Sudan is though intensification of the African Monsoon and its increased penetration into 202 northern Africa. The last interglacial period coincided with a very strong northern hemisphere 203 solar insolation maximum, which greatly enhanced the intensity of the summer monsoon in the 204 northern hemisphere (Rossignol-Strick, 1983). This super monsoon occurred at a time when sea 205 level likely exceeded 8 m higher than present (Rohling et al., 2008) and mean temperatures were 206 up to 2 °C higher than present. The accompanying increased precipitation was capable of 207 transforming this section of the Sahara into a wet, vegetated landscape.

1 SUPPLEMENTAL METHODS

2 **EXPOSURE DATING**

3 To sample the shoreline we selected a site about 280 m west of the nearest inselberg 4 (Jebel Hawaja; Figure 2) to reduce the possibility of slope wash reaching the sample site. 5 Aerial images show slope wash halos around the inselbergs and a post-depositional alluvial 6 fan 2 m thick flanking the inselberg and extending over the adjacent shoreline to at least 100 7 m. A 3 m trench (Section S2 of Williams et al. (2010)) was excavated using a bulldozer and 6 8 samples were collected at 0.5 m intervals down the pit wall. Field observations and particle 9 size analysis at site S2 (Figure 2) show a decrease in gravel content and an increase in sand 10 from the base upwards, consistent with lake retreat, a decrease in wave energy and final 11 deposition of a sandy beach at the site. A well developed soil has subsequently formed on top of the shoreline sediment. 12

13 The granite was crushed and a coarse quartz concentrate was prepared using heavy 14 liquids and magnetic separation. Only the coarse sand (>0.5 cm) and gravel fraction of the 15 shoreline sediment was used for ¹⁰Be analysis. We purified quartz and extracted ¹⁰Be using 16 standard methods (Barrows et al., 2001). The surface sample was run in duplicate. Isotopic 17 ratios (¹⁰Be/Be) were measured by accelerator mass spectrometry on the 14UD accelerator at 18 the Australian National University.

To investigate the potential for sequential deposition of the shoreline and to quantify inheritance of cosmogenic nuclides in the sand and gravel, we used a profile dating approach. Prolonged exposure of a sediment column to cosmic rays produces a characteristic cosmogenic nuclide depth profile that is a function of the production rate of the nuclide, sediment density, the accumulation or erosion rate of the sediment, and inherited nuclides in the sediment from previous exposure at the sediment source. Ideal conditions for exposure

25 dating a profile are rapid deposition, an absence of post-depositional accumulation or erosion 26 of the surface, and rapid erosion rates at the sediment source, which delivers a minimal inherited nuclide component. The setting of the Jebelein shoreline satisfies these suitability 27 28 criteria. The ridge represents a high-energy depositional environment and therefore was 29 deposited in a brief period of time. Second, there is no geomorphic evidence for widespread 30 erosion of the surface in the form of gullying. Third, there appears to have been limited post-31 depositional accumulation of sediment on the surface. However, inheritance is likely to be significant because weathering rates are low on inselbergs in desert environments (e.g., 32 33 Bierman and Caffee (2002)).

34 Cosmogenic nuclide production rates are a topic of active research and as yet no consensus has emerged as to a ¹⁰Be production rate and a single scaling scheme that is 35 globally applicable. The CRONUS calibration data set gives a ¹⁰Be production rate by 36 spallation of 4.49 \pm 0.39 atom g⁻¹a⁻¹ at high latitude and sea level using the (Stone, 2000) 37 38 scaling scheme (Balco et al., 2008). However, recent calibrations indicate that this rate is too high by at least 10% (Balco et al., 2009; Fenton et al., 2011; Kaplan et al., 2011; Putnam et 39 al., 2010). In the absence of a regional production rate calibration, we used the North 40 41 American regional production rate of Balco et al. (2009) which is at a similar elevation (<500 42 m) and within uncertainties is the same as the other recent Northern hemisphere calibration 43 (Fenton et al., 2011). It also has a longer calibration exposure age incorporating more 44 geomagnetic variability. To scale the production rates we use the scaling scheme of (Lifton et 45 al., 2005). Barrows et al. (2013) have shown that the Lifton et al. (2005) scheme produced the best match between ¹⁰Be and radiocarbon dates in New Zealand. The calculated ¹⁰Be 46 47 concentrations, ages and weathering rates are given in Supplemental Table 2.

48 To determine the exposure age for the profile, we updated the coefficients of the 49 equations used in Granger and Smith (2000) for the ¹⁰Be production rate of Balco et al.

(2009) from that of Stone (2000). Maximum likely inheritance on the gravel was determined
by processing three samples from the top of the adjacent Jebel Hawaja. The morphology of
the inselbergs at Jebelein, including exfoliation and solution pits, indicates a low long-term
weathering rate.

54 The uppermost part of the section appears to be reworked. OSL dating of fine sand in 55 the surface soil at a depth of 56 cm yielded an apparent age of 3.0-3.1 ka. Fine sand from 106 56 cm showed very high dispersion and had equivalent dose values at about 1.5 Gy and 120 Gy, 57 corresponding to ages between 2.0 ka and 158 ka (Williams et al., 2010). Additionally a 58 portable dolerite murhakah (lower grinding stone) was found within the soil after excavation, 59 but from an unknown depth. The age of this grindstone is difficult to determine because their 60 use extends from the upper Palaeolithic through to the recent. Dozens of grinding holes and 61 thick camp site hearth deposits of charcoal and broken bone line the edges of nearby 62 inselbergs adjacent to the Nile River and indicate an important site of Neolithic habitation during a time when grassland was more widespread, probably before 4,500 ¹⁴C yr BP. We 63 therefore consider it likely that the grindstone was incorporated into the profile during the 64 65 mid Holocene and therefore the upper part of the sediment profile was probably reworked at this time. It is also possible that some slope wash from the inselberg has reached the site and 66 lowered the mean ¹⁰Be concentration of the surface sediment. For these reasons we chose to 67 analyse the coarse sand and gravel which has a much lower potential for translocation both 68 up and down the profile. Our logging showed that original bedding of the coarse clasts is 69 70 intact below the surface of the soil (Fig. 2).

We used the CRONUS online calculator (Balco et al. 2008) to calculate the ¹⁰Be production rate at the site. The exposure age (together with inheritance) was calculated from a least squares fit of a curve that is a sum of exponentials representing spallation, slow muon

capture and fast muons (Granger and Smith, 2000). Because the relative errors are similar on
each sample, we did not weight the fit.

The density of the sediment varies through the profile and so it was not possible to determine an integrated mean density for use in the calculations. The density of sand and gravel mixtures ranges from 1.6-2.1 g/cm³, so we chose a density of 1.9 g/cm³. Variations of 0.1 g/cm³ in density change the exposure age by ~2 %. A density of 2.7 g/cm³ was used for the granite samples. The quoted uncertainties are 68% confidence limits incorporating all known sources of measurement error, and include fully propagated production rate errors.

82 OPTICALLY STIMULATED LUMINESCENCE

Seven samples were collected for optically stimulated luminescence (OSL) dating from channel sands and overlying sediments, and one sample was collected from the modern White Nile to assess the extent to which the OSL signal is reset at deposition in this environment. Samples were collected by inserting an opaque tube into the sediment. This was then sealed at both ends and wrapped in black plastic. In the laboratory the material from both ends of the tube, which would have been exposed to light, was scraped out and used for environmental dose rate measurements.

90 Samples were processed either at Aberystwyth University or at the University of Adelaide. The comparability of the two sets of analysis has previously been demonstrated 91 92 (Macklin et al., 2013). Samples were prepared using similar procedures in both laboratories. 93 Samples were initially treated with hydrochloric acid to digest carbonates and hydrogen 94 peroxide to remove any small amounts of organic material. Grains in the ranges 180-212 µm 95 (Aberystwyth) and 125-180 µm (Adelaide) were selected by dry sieving. Solutions of sodium 96 polytungstate were used to isolate grains with a density between 2.62 and 2.70 g/cm³. Grains 97 were etched for 40 minutes in 40% hydrofluoric acid to remove feldspar and other non-quartz 98 material and to remove the outer 9 μ m of the quartz grains. This eliminates the effect of alpha 99 particle contribution to the irradiation of the grains. The material was then re-sieved to 100 remove any remaining feldspar grains. All the laboratory procedures were carried out in 101 subdued red light.

102 In Adelaide, uranium (U), thorium (Th) and potassium (K) concentrations were measured by Genalysis Laboratories, Perth, using Inductively Coupled Plasma Mass 103 104 Spectroscopy (ICPMS) for U and Th, and Inductively Coupled Plasma Atomic Emission 105 Spectrometry (ICPAES) for K. U and Th concentrations were also measured by thick source 106 alpha counting (TSAC) in the Adelaide laboratory, and K concentrations by CSIRO 107 laboratories, Adelaide, using X-ray fluorescence spectroscopy (XRS). The cosmic ray 108 contribution was obtained using the relationship between cosmic ray penetration, depth and 109 latitude determined by (Prescott and Hutton, 1994). The radionuclide concentrations obtained 110 by the various methods were averaged, and the dose rate to be used in the age calculation, as 111 well as the beta and gamma contributions to this dose rate, was determined using the AGE 112 program of Grün (see Grün (2009)).

113 In Aberystwyth, beta dose rate was determined using a Risø beta counter (Bøtter-Jensen and Mejdahl, 1988), and the concentration of U, Th and K in the samples was 114 115 determined using geochemical methods. For each sample, a finely milled sub-sample was 116 fused using a sodium metaborate flux and put into solution. The resulting solutions were 117 analysed using ICP-OES to determine the concentration of K and ICP-MS to determine the 118 concentration of U and Th. The conversion factors of Adamiec and Aitken (1998) were then 119 used to calculate the gamma dose rate. The cosmic ray contribution was obtained using the 120 relationship between cosmic ray penetration, depth and latitude determined by Prescott and 121 Hutton (1994). Water content of the material as received was measured by weighing, drying overnight at 180°C, and re-weighing. A value of $5 \pm 2\%$ was used as the best estimate of the 122

water content during the period of burial for all samples except the sample from the modern White Nile where a value of $10 \pm 5\%$ was used (Note: an increase of 1% in the water content causes an increase of approximately 1% in the measured age of the sample). The results of these measurements, and the calculated dose rates, are given in Table S3.

Luminescence measurements for sample S10/5-2 were carried out at the University of
Adelaide, and the other six samples including the surface sample were measured at the
Aberystwyth Luminescence Research Laboratory (ALRL) at Aberystwyth University.

130 Luminescence measurements in Adelaide

131 In Adelaide luminescence measurements were made on small aliquots consisting of 132 between about 50 to 100 grains in the 125-180 µm range. Pilot studies had indicated that this 133 number of grains would enable individual differences between the aliquots to be detected, 134 while still providing measurable luminescence. Luminescence measurements were carried out using a Risó TL/OSL-DA-20 reader. Radiation was applied using a calibrated 90 Sr/ 90 Y β 135 source delivering a dose rate of 0.135 Gy/sec. Luminescence was stimulated using blue light-136 137 emitting diodes (wavelength 470 nm) and detected using an EMI 9235QB photomultiplier and 138 Hoya U340 filter. The measurement procedure followed the single aliquot regeneration 139 (SAR) protocol described by Murray and Wintle (2000). Four regeneration doses were used, 140 selected on the basis of a pilot study, plus a zero dose point to test for recuperation, a repeat 141 of the first dose to test for acceptable recycling and a second repeat of the first dose followed 142 by exposure to infra-red radiation to test for the absence of feldspars (IR depletion test). 24 143 aliquots were run, and those having recycling ratios greater than 0.85, recuperation less than 144 0.15 and IR depletion ratio less than 0.15 were accepted for analysis. 23 out of the 24 aliquots passed the screening criteria. The equivalent dose De was determined for each aliquot by 145 146 interpolation of its dose response (luminescence vs dose) curve. The equivalent dose is the

147 laboratory-applied dose that produces luminescence equal to that of the natural sample and is148 hence equal to the total burial dose.

The individual D_e values showed a fairly well constrained distribution with six clearly outlying high values. The D_e values were combined, omitting the outliers, using the central age model (CAM) to derive a final D_e value for age calculation.

152 Luminescence measurements in Aberystwyth

153 In Aberystwyth luminescence measurements were made on aliquots containing ~500 grains of quartz between 180-211 µm in diameter. A Risø TL/OSL reader model TL-DA-15 154 155 was used for measurements. Blue LEDs (470A20 nm) were used for optical stimulation, and 156 the resulting OSL was detected using an EMI 9635QA photomultiplier fitted with 7.5mm of 157 Hoya U-340 filter. The resulting OSL signals showed a rapid initial decrease in intensity (Fig. 158 S1a) as would be expected from samples where the OSL signal is dominated by the fast 159 component. As in Adelaide, the SAR method was used, and typically 6 to 7 regeneration 160 doses were used to characterise the dose response curve and calculate the equivalent dose 161 (D_e) for each aliquot (Fig. S1b). Uncertainties on individual D_e values were determined using 162 the approach outlined in Duller (2007) which incorporates the uncertainty due to counting 163 statistics on each individual OSL decay curve, the uncertainty in the curve fitting procedure, 164 and also a 1.5% uncertainty associated with the Risø instruments used for these 165 measurements. Twenty-four replicate measurements of D_e were made for each sample. Data 166 was screened using standard acceptance criteria, including (1) a recycling ratio within 10% of 167 unity, (2) an IR depletion ratio (Duller, 2003) within 10% of unity, (3) a net OSL signal from 168 the test dose that is at least three times larger than the standard deviation of the background, 169 (4) a dose response curve that increases monotonically and (5) a natural signal (and 170 associated uncertainty) that intersects with the dose response curve. This screening removed 171 very few aliquots, with between 21 and 24 aliquots passing all of these criteria.

172 The modern sample from the White Nile (S11/WN1) gave an age of 0 ± 21 years, 173 demonstrating that quartz is very effectively reset by exposure to daylight at the time of 174 deposition in this environment. One of the limitations of luminescence dating is the impact of 175 saturation of the OSL signal at high doses. The form of the dose response curve (Fig. S1b) is 176 either a single saturating exponential, or the sum of two saturating exponential functions. As 177 the radiation dose to which a sample is exposed increases, the rate of growth of the OSL 178 signal decreases, until at some point there is negligible growth. Beyond this point it is not 179 possible to resolve samples of different age. A number of the samples in this study have large 180 D_e values (> 100 Gy, Table S4), but no more than 2 aliquots from 24 measured for each 181 sample failed because the OSL signal was saturated. However, one feature of the samples 182 with a high D_e (> 100 Gy) is that they tend to have dose distributions (Fig. S1c) with 183 overdispersion values (25-30%) slightly higher than is normally encountered in younger 184 samples, and this is thought to result from curvature of the dose response curve. There is no 185 evidence that this overdispersion is related to incomplete resetting of the luminescence signal 186 at deposition, and the age of 0 ± 21 years for the modern sample supports this. Therefore, the De values for each sample were combined using the central age model (CAM) to derive a 187 final D_e value for age calculation. The equivalent doses, dose rates and ages for all the 188 luminescence samples are summarised in Table S4. 189

190 **I**

LAKE RECONSTRUCTION

The SRTM90m digital elevation model (DEM) released by NASA has a 3 arc second horizontal resolution and a ~5 m vertical precision in this region, and was used to map the White Nile River valley in ARCGIS (Fig. 1). Palaeoshorelines are obvious in many areas and were mapped directly from the DEM. The height of the shoreline drops by ~5 m over a distance of 400 km, indicating a gradient of ~ 1:80,000. This is due to incomplete damming of the lake. Contours were generated at 395 m in the lower catchment and 400 m in the upper 197 catchment, which showed the best fit to the top of the shorelines. This allowed for the 198 shoreline of the entire lake to be extrapolated to where shorelines were absent. The area and 199 volume of the palaeolake were calculated in GIS by filling the valley to the appropriate 200 height, whilst taking into account the underlying topography.

Site	Sample	External β dose 'wet' (Gy/ka)	External γ dose 'wet' (Gy/ka)	Cosmic dose (Gy/ka)	Total dose rate (Gy/ka)	Equivalent dose (Gy)	Age (ka)
В	S11/1-1	0.99 ± 0.04	0.45 ± 0.02	0.18 ± 0.02	1.62 ± 0.05	112 ± 6.2	69 ± 4
В	S11/1-2	0.90 ± 0.04	0.41 ± 0.02	0.17 ± 0.02	1.48 ± 0.04	130 ± 6.2	88 ± 5
В	S11/1-3	0.83 ± 0.04	0.38 ± 0.02	0.16 ± 0.04	1.36 ± 0.06	140 ± 10	103 ± 9
С	S10/5-2	0.79 ± 0.05	0.48 ± 0.05	0.19 ± 0.02	1.47 ± 0.04	15.3±1.5	10.4 ± 1.1
С	S10/5-3	0.71 ± 0.03	0.36 ± 0.02	0.17 ± 0.02	1.24 ± 0.03	141 ± 9.6	113 ± 8
С	S10/5-4	0.85 ± 0.04	0.34 ± 0.01	0.17 ± 0.02	1.36 ± 0.04	156 ± 13	115 ± 10
D	S11/3-1	0.80 ± 0.03	0.38 ± 0.02	0.19 ± 0.04	1.36 ± 0.05	142 ± 7.0	104 ± 6
E	S11/WN1	0.65 ± 0.04	0.30 ± 0.02	0.30 ± 0.03	1.25 ± 0.06	0.00 ± 0.02	0.00 ± 0.02

Supplemental Table S4. Dose and dose rates for optical ages

Note:

Grain Size 180-211 μ m for all samples except S10/5-2 for which grains 150-180 μ m in diameter were used.

Figure S1: Luminescence characteristics of a typical sample (S10/5-3). (a) Natural OSL decay curve. Note the log scale on the y-axis, (b) dose response curve and (c) radial plot showing the distribution of D_e values. (a)
