Executive summary

Background

Foot and ankle devices are being developed as a method of preventing people with sensory perception loss sustaining a fall. Such devices are believed to work by reducing the likelihood of a fall by improving the balance and gait of the user.

Objectives

Evaluate the effectiveness of foot and ankle devices for the prevention of falls and the improvement of balance and gait in adults with sensory perception loss.

Inclusion criteria

Types of participants

Participants were community dwelling adults with bilateral pathological sensory perception loss.

Types of intervention(s)/phenomena of interest

This review evaluated any foot or ankle device, including but not restricted to all types of footwear (therapeutic, retail), insoles (customized, prefabricated) and ankle foot orthoses.

Types of studies

In the absence of randomized controlled trials, the review considered experimental and epidemiological study designs, except case series, individual case reports and descriptive cross sectional studies.

Types of outcomes

The primary outcome was number of falls. Secondary outcome measures included clinical or laboratory measures of balance or gait.

Search strategy

A search for published and unpublished literature from inception to March 2015 written in the English language was conducted across a number of major electronic databases. A three-step search strategy was developed using MeSH terminology and keywords to ensure all relevant material was captured.

Methodological quality

Methodological quality of included studies was assessed by two reviewers, who appraised each study independently, using standardized Joanna Briggs Institute (JBI) critical appraisal tools.

Data extraction

Quantitative data was extracted from the studies that were identified as meeting the criteria for methodological quality using the standardized JBI data extraction tools.

Data synthesis

Due to the heterogeneity of populations, interventions and outcome measures meta-analyses were not possible and results are presented in narrative form.

Results

Nine trials (from ten papers) involving 238 participants, (14 with multiple sclerosis and 16 with idiopathic peripheral neuropathy, 150 with diabetic neuropathy) and 58 controls were included in the review. No study reported falls as an outcome measure. The results of the included studies found that in people with sensory perception loss, postural sway improved with vibrating insoles and ankle foot orthosis (AFOs); altering the softness and texture of the top cover had no effect on postural sway; wearing footwear over long distances or AFOs improved step to step consistency; and no foot and ankle device was reported to have a negative effect on the balance or gait of people with sensory perception loss. The methodological quality of the included studies was poor. No study used a RCT methodology. No study incorporated a follow up period or tested the intervention within the context of the intended clinical environment.

Conclusions

There is limited evidence to suggest that footwear and insole devices can artificially alter postural stability and may reduce the step to step variability in adults with sensory perception loss. Varying the material properties of an insole does not notably affect static balance or gait.

Keywords

balance, falls, gait, insoles, orthotics, footwear, neuropathy

Background

Sensory perception loss in the lower limbs is commonly associated with a number of chronic conditions including diabetes, neurological, and autoimmune diseases.¹⁻⁴ Peripheral neuropathy associated with diabetes is the most common cause of sensory perception loss, affecting up to 50% of individuals with the condition.⁴ Altered somatosensory input can have major implications on postural control. At the feet, reduced information about the supporting surface or altered awareness of lower limb positioning, can impair the ability to successfully respond to threats to balance. These sensory changes, commonly observed in ageing populations, can be accelerated in adults with pathological loss of foot sensation,^{3, 5} increasing their risk of falls and injury.⁶⁻⁸

Falls are a major public health issue for adults with sensory perception loss. In people with diabetes, many of whom present with peripheral neuropathy, up to 39% of those aged over 65 years⁸ and 35% of those above 55 years,⁹ are reported to fall annually. Whilst pathological sensory loss cannot be reversed, one potential modifiable external fall risk factor is the interface between the foot or ankle and supporting surface. Foot and ankle devices including footwear, insoles, and ankle foot orthoses, (AFO) are all modalities which can be manipulated to alter this interface, and potentially an individual's propensity to falling. Indeed, several studies show that wearing suboptimal footwear is an influential factor contributing to slips, trips and falls in older people.¹⁰ Notably, inappropriate footwear has been reported in up to 75% of people who experience a falls-related hip fracture.¹¹

Foot and ankle devices, including shoe insoles and AFO's have been shown to alter standing balance,¹² gait kinetics and kinematics¹²⁻¹⁴ in healthy young,¹³ ageing¹², rheumatoid arthritic¹⁵ and diabetic neuropathic¹⁴ populations. Whilst their mechanism of action remains unclear, current theories suggest footwear interventions may bring about their effects by way of providing mechanical support, shock attenuation, and alterations in sensorimotor control, or a combination of all.^{16, 17} Mechanoreceptors located in the plantar surface of the feet provide important sensory information about changes in the position of foot pressure, which is used to inform maintenance of upright body position. However, plantar sensory thresholds are reduced with increasing age^{18, 19} and further compromised in those with pathological sensory perception loss.^{3, 20} As such, a wide range of shoe insole devices have been developed with a view to enhance residual sensory information at the lower limbs, for improving balance control and gait in insensate populations.²¹⁻²⁶ Insoles can be defined as any material construction positioned within a shoe, on which the foot rests. Insoles can be prefabricated or custom-made devices and include a variety of profiles ranging from form-fitting to flat insoles.

To date, three systematic reviews have been conducted addressing the impact of insoles^{12,27} and footwear features¹⁰ on measures of balance and falls risk in ageing populations, including those with peripheral nervous system disorders.²⁷ However, despite the major clinical and functional implications of sensory perception loss, the role of footwear interventions in this patient group has not been addressed using systematic review methodology. The prescription of therapeutic footwear and insoles plays a pivotal role in the management of people with peripheral neuropathy, as a means to reduce areas of high plantar pressures and prevent the development of foot ulceration.²⁸ Whilst this preventative strategy aligns with recommendations from the National Institute for Health and Care Excellence (NICE) guidelines²⁹ and a Cochrane review of the data,³⁰ the potential benefits (or otherwise) of such footwear interventions on balance, gait or falls risk, remains unknown.

Laboratory and clinical-based measures of balance and gait have been used to explore the effects of wearing footwear interventions on postural control mechanisms.^{12, 31-33} During static balance tasks, such as standing quietly in a comfortable position (unperturbed), on a force platform, the magnitude and velocity of centre of pressure (CoP) movement in mediolateral and anterior-posterior axes, have been extracted to quantify the effect of insoles and footwear.¹² Notably, CoP velocity is reported to be one of

the most sensitive measures in detecting between-condition differences in balance control.³⁴ Other traditional sway parameters, such as mean speed and amplitude of the CoP, have been used in previous trials to predict falls.³⁵ Clinical assessments of mobility and functional task performance enable clinicians to observe balance control during demanding postural challenges which simulate those encountered in daily life.^{36, 37} Such balance tests include the functional reach and berg balance scale, with the former reported to be a predictor of falls and sensitive to change following the introduction of an intervention.^{38, 39} Further, modifications in walking patterns have been associated with falls in ageing populations.⁴⁰ Older fallers frequently adopt a more conservative gait pattern, showing marked reductions in velocity and step length, increased step width and variability.^{41, 42} Therefore, spatiotemporal gait parameters commonly feature as primary outcome measures in studies evaluating the effect of an intervention on falls risk.^{12, 43, 44}

The aim of this review was threefold. First, the review aimed to highlight balance and gait deficits and falls risk for consideration by health care professionals when prescribing foot and ankle devices to people with loss of foot sensation. Second, this review set out to establish the therapeutic benefits (or otherwise) of foot and ankle devices on laboratory and clinical measures of balance, mobility, and falls, within clinical populations with sensory perception loss. Third, the results of this review will be used to identify any footwear interventions and design features which have the capacity to alter balance, gait and reduce falls. This knowledge will be used to guide the future prescription and development of foot and ankle devices for people with pathological sensory perception loss. This review was conducted according to an *a priori* published protocol.⁴⁵

Objectives

The primary and secondary objectives of this systematic review were to:

1. Synthesize the best available evidence regarding the effects of foot and ankle devices on falls in adults with pathological, bilateral lower limb sensory perception loss.
2. Evaluate the effect of foot and ankle devices on the surrogate secondary measures of falls risk, with regard to: i) gait and ii) balance in adults with pathological, bilateral lower limb sensory perception loss.
3. Generate knowledge to inform the development of a new footwear device for people at increased risk of balance impairments and falls due to loss of foot sensation.

More specifically the review content provides a summary of current evidence regarding the effect of foot and ankle devices (including therapeutic and retail footwear, prefabricated and custom-made insoles and ankle foot orthosis) on fall frequency or incidence, and clinical or laboratory measures of balance and gait, in adults with sensory perception loss.

Inclusion criteria

Types of participants

This review considered studies that included participants who were community dwelling adults over the age of 18 years old with bilateral sensory perception loss, defined as being unable to feel a 10g monofilament at one or more sites on the plantar surface of the foot.⁴⁶

Exclusion criteria

- People with foot ulceration at the time of the study
- People with unilateral sensory perception loss
- People from hospitals or care homes
- People with an upper motor neuron injury (e.g. stroke survivors)
- People with age-related loss of foot sensation that did not originate from pathology.

Types of intervention(s)/phenomena of interest

This review considered studies that evaluated the effect of any foot or ankle device on balance, gait or falls in adults with sensory perception loss. Foot or ankle devices were defined as any device placed in direct contact with the foot or ankle. This included therapeutic and non-therapeutic footwear, insoles designed to increase mechanical support or afferent sensory feedback, AFO and ankle braces used to restrict joint motion. In this review, studies were included if they presented one of the following comparisons: i) foot or ankle device is compared to another foot or ankle device or; ii) foot or ankle device is compared to no intervention/control condition.

Studies that included any of the following interventions were excluded from the review:

- Industrial safety footwear
- AFO which extended to the level of, or beyond, the knee joint
- Foot ulcer offloading devices.

Outcomes

Studies which reported any measure of falls frequency or incidence were eligible for inclusion in the review. This review also considered studies that included any standardized clinical measures (e.g. Berg Balance Scale, ³⁶ Functional Reach ³⁷) or laboratory-based assessment (e.g. centre of pressure movement³⁴) of static or dynamic standing balance. Similarly, studies which measured gait by way of clinical tests (e.g. Timed Up and Go Test, ⁴⁷ Dynamic Gait Index ⁴⁸) or laboratory assessments (e.g. spatiotemporal gait parameters ⁴¹) were included in the review.

Types of studies

The review considered experimental and epidemiological study designs including randomized controlled trials, non-randomized controlled trials, quasi-experimental, before and after studies, prospective and retrospective cohort studies, case control studies and analytical cross sectional studies. Descriptive epidemiological study designs including case series, individual case reports and descriptive cross sectional studies were excluded from the review.

Search strategy

The search strategy aimed to find both published and unpublished studies. A three-step search strategy was utilized in this review. An initial limited search of MEDLINE, and EMBASE (OVID) was undertaken followed by analysis of the text words contained in the title and abstract, and of the index terms used to describe the articles. A second search using all identified keywords and index terms was undertaken across all included databases. Thirdly, the reference list of all identified reports and articles was searched for additional studies. Studies published in the English language were considered for inclusion in this review. Studies published from inception to March 2015 were considered for inclusion in this review.

The sources searched included:

MEDLINE, Embase (OVID), CINAHL, AMED (EBSCO), The Cochrane Central Register of Controlled Trials and the JBI Database of Systematic Reviews and Implementation Reports.

The search for unpublished studies included:

Google Scholar, a thesis database (<http://www.thesis.com>), BIOSIS, Zetoc (<http://zetoc.jisc.ac.uk.plymouth.idm.oclc.org/wzgw?db=etoc>) and EThOS .

Initial MESH and key terms used related to foot orthosis and insoles, footwear and shoes, ankle foot orthosis and ankle braces, postural balance and body sway, gait and walking pattern, stabilising and destabilising, accidental falls, older persons, nervous system disorders, diabetes and neuropathy

An example of a full search strategy used in a major database is provided in Appendix I.

Method of the review

All studies selected for retrieval were assessed by two independent reviewers for methodological validity prior to inclusion in the review. A list of the full text articles that were assessed for eligibility can be found in Appendix II. Each paper was assessed using standardized critical appraisal instruments from the Joanna Briggs Institute Meta-Analysis of Statistics Assessment and Review Instrument (JBI-MAStARI) (Appendix III). Where disagreements arose between the reviewers, these were resolved through discussion until agreement was reached. When it was unclear if study participants were assessed as having pathological sensory perception loss, the corresponding author of the article was contacted for clarification. In total eight authors were contacted and six responded. When no response was received from an author the corresponding article was excluded.

Data extraction

Quantitative data were extracted from papers included in the review using the standardized data extraction tool from JBI-MAStARI (Appendix IV). The data extracted included specific details about the interventions, populations, study methods and outcomes of significance to the review question and specific objectives.

Data synthesis

Quantitative data analysis by way of statistical pooling was not possible, due to the wide and heterogeneous range of study methods and outcome measures used across the included studies. Therefore, the findings of this review were presented in narrative form, with general themes established in the discussion.

Results

Description of studies

The flow chart below (Figure 1) details identification and selection of studies. All citations, abstracts, and papers were independently scanned by two investigators (JP and AH). The search produced 231 papers including three duplications. Three additional papers were identified from other sources; two from Google Scholar and one from BIOSIS. Screening by title of the remaining 231 citations excluded

154 records leaving 77 abstracts to screen. From this 33 potential articles were identified. A further 21 papers were excluded on full text review. Twelve papers underwent critical appraisal by the two investigators. Two were excluded because of quality issues. A total of ten papers reporting on nine studies met the inclusion criteria and were included into the review. Appendix II summarizes the details of the retrieved studies and Appendix V lists the studies that were excluded following assessment of the full text article, together with the reason for exclusion. The primary reasons retrieved studies were excluded from the review were because study participants were not identified as having a pathological level of sensory perception loss.

Study characteristics

Study characteristics are reported in Appendix VI. A total of 238 participants (58 controls) were included in nine laboratory based observational trials, 99 in the intervention group were male and 81 were female.^{21, 22, 24, 26, 50-55} Two of the ten articles included publications reporting on the same trial and participant group and therefore the data contained were merged.^{24, 54} The number of participants recruited to the intervention group in each study ranged from 11 to 42. The mean (Standard Deviation) age within treatment groups ranged from 41.8 +/- 7.3 to 69.5 +/- 14.1 years. Six studies^{21, 22, 26, 51, 53, 55} recruited people with diabetic peripheral neuropathy, one study⁵⁰ reported on people with multiple sclerosis and two studies^{24, 52} used people with sensory perception loss of mixed pathology.

There were four comparisons made to foot and ankle devices including, no foot and ankle device^{26, 50, 52-54} barefoot,⁵¹ standard diabetic insole⁵⁵ and the intervention (vibrating) insole turned off.^{21, 22} Five studies^{21, 22, 26, 50, 56} reported testing various insole designs/concepts including insoles that vibrated,^{21, 22} insoles with a rough top surface (sandpaper),⁵⁰ offloading moulded insoles with a novel anti-shear cover,⁵⁵ and a comparison of two flat insoles with differing (hard and soft) shore values.²⁶ Three studies^{24, 52, 53} reported testing AFOs. One offered mechanical support in the medial lateral direction,²⁴ the other two studies conducted by the same research group tested a single AFO intervention offering minimal ankle support in the sagittal plane but instead was designed to provide sensory stimulation via the shank to the lower leg.^{52, 53} One study used participants usual footwear as the intervention.⁵¹

Methodological quality

Assessment of methodological quality is reported in Table 1. Two studies were rejected after the review of full text because of quality issues. One study²⁵ used unreliable outcome measures. A second study⁵⁷ failed to adequately describe the allocation of the intervention group such that it was difficult to differentiate between participants wearing footwear with those in cast/offloading devices.

None of the studies reported falls as an outcome measure. Instead, five used parameters of balance measured in static stance,^{21, 22, 26, 52, 53} and four studies used gait kinematic, spatial and temporal measures,^{24, 50, 51, 55} with one study including lower limb electromyography (EMG).⁵⁰ Parameters of balance included velocity of centre of pressure (COP),²² Root Mean Square of COP velocity,^{22, 26} stabilogram radius and area,²¹ range of COP excursion²¹, sensory organization test.^{52, 53} The main outcome measures in all studies excluding one were clearly described and recorded in a reliable way using objective assessment tools.⁵³ All the studies investigated the immediate effect of the foot or ankle device presented in a random order during a single data collection. None of the studies included a follow up period. None of the studies reported conducting a priori sample size analysis to recruit sufficient participants to identify a significant difference between groups. In all but one study the sample size appeared deficient (n<40).²⁴ Whilst appropriate methods of statistical analysis were selected according

to study design, parametric methods were consistently applied to sample sizes better suited to nonparametric analysis.

Five of the included studies were comparable cohort or case control studies.^{21, 22, 26, 50, 51} These five studies were conducted using a convenience sample of participants with sensory perception loss, although limited detail was given about the population from which they were drawn. Statistical tests of significance assumed baseline comparability of confounding factors between groups. Four of the five studies^{21, 22, 50, 51} attempted to address confounding factors between groups by recruiting a healthy control group that was matched for age and sex. One study recruited a control group of comparatively young (mean age 37 years) males used only as a point of reference and not included in the analysis.²⁶ Confounding factors between groups in this study were insufficiently addressed. In all studies comparison of intervention effect was analyzed with the participant acting as their own control. Blinding of the intervention to participants and researchers was therefore not possible. Four of the studies compared one intervention with a control condition, usually no intervention.^{21, 22, 50, 51} One study compared two 8mm insole interventions (a soft foam insole shore value 15 and a hard multiform insole shore value 30) with the control.²⁶

The other four studies were repeated measure studies.^{24, 52, 53, 55} Generally, insufficient information was reported regarding the source population of these four studies. All of the studies made clear the criteria for participant inclusion. One of the limitations of pre and post intervention design is that blinding to the intervention is not possible.⁵⁸ Three of the studies compared one intervention with a no intervention condition.^{52, 53, 55} One study compared three interventions (AFO, walking cane and touching a vertical surface) with a no intervention condition.²⁴ Only data relating to the effects of the AFO are considered within the scope of this systematic review.

The information reported in all studies was sufficient to make some assessment of study outcome and included a reasonable description of interventions, main outcomes and findings.

Findings of the review

The studies included within this review were too heterogeneous to be combined for meta-analysis. Studies differed in terms of participant characteristics, intervention and outcome measures, therefore findings will be presented in a narrative form. A summary of the results, conclusions and characteristics of included studies can be found in Appendix VI.

Comparison 1: Insoles with vibrating component activated versus insoles with vibrating component immobilized

Activated vibrating insoles (turned on) were compared with immobilized vibrating insoles (turned off) for people with diabetes and neuropathy in two studies,^{21, 22} including 32 people with diabetes and neuropathy and 27 healthy older adults. Both studies measured the effect of the insoles on postural sway. One study recorded mean and maximum stabilogram radius, area and range in the anterior posterior and medial lateral direction using a marker attached to the right shoulder, quiet standing with eyes closed only.²¹ Whilst the other used force plate stabilometry to record Root Mean Square COP velocity in anterior posterior and medial lateral directions with eyes open, eyes closed and whilst performing a dual task.²²

Both studies reported increased sway in people with diabetes and neuropathy when compared to controls. One trial ²¹ reported a significant reduction in all sway parameters measured with eyes closed in both groups with vibration activated, although absolute values or the size of the difference were not fully reported. The other trial ²² found no difference between insole conditions with the exception of anterior posterior sway in the group with diabetes and neuropathy. However, this difference was only evident when balance was challenged by simultaneously removing visual cues and diverting attention. Under these test conditions the root mean square COP velocity in the anterior posterior direction reduced from 24.3 to 20.4 mm/s when the vibration was activated.²² Both studies provide evidence that vibrating insoles may reduce sway in people with diabetes and neuropathy when other compensatory balance strategies are compromised.

Comparison 2: Insole top cover material type verses standard intervention for people with sensory perception loss

Insole top cover materials with different material properties e.g. softness or texture, was compared with standard offloading insole or no insole condition for people with sensory perception loss in three studies ^{26, 50, 55}, including 14 people with multiple sclerosis and sensation loss, 57 people with diabetes and peripheral neuropathy and 10 controls.

One study ⁵⁰ compared flat shoes without socks whilst walking with and without fine leather insoles covered with grade p80 wet and dry sandpaper in 14 people with multiple sclerosis and sensory loss. The addition of the rough textured insole made no difference to gait velocity or cadence, EMG activity or the majority of kinematic gait parameters. A significant increase in ankle joint dorsiflexion, and total hip and knee excursion angle was reported when textured insoles were worn. However, the recorded mean difference between conditions were small (measuring 0.6, 1.4 and 0.8 degrees respectively).

A second study ²⁶ compared an 8mm thick foam insole, shore value 15, and a harder 8mm multiform insole, shore value 30, with a no insole condition in 30 people with diabetes and neuropathy and 10 controls. No more detail about the insole material tested was published. The authors reported increased anterior posterior COP velocity in the people with diabetes and neuropathy, and in both groups with eyes closed, but not whilst performing a dual task. There was no difference in root mean square value of the anterior posterior velocity of the COP in either group when the no insole, soft and hard insole conditions were compared.

A third study ⁵⁵ compared a custom made moulded hard Ethylene-vinyl Acetate (EVA) insole covered in a four way stretch neoprene rubber and containing a sliding sandwich of silicone at the forepart, with a custom-made standard firm density Plastazote moulded insole covered in PPT® (a cross linked polyethylene foam) in 27 people with diabetes and neuropathy. The authors reported on 12 different gait parameters recorded under single and dual task conditions and three static balance measures of sway conducted with eyes open and eyes closed. There was no difference in any of the gait or static balance measures between insoles with the exception of double stance time during gait initiation. Double stance time at gait initiation (defined as the acceleration phase occurring when moving from a standing position to walking) reduced from 32% to 28% of the gait cycle.

There is evidence to suggest that the properties of the top cover material (roughness, softness or horizontal stretch/shift) selected for insole fabrication does not have an effect on the static balance of

people with sensory perception loss. There is limited evidence to suggest roughness and horizontal stretch/shift of the top cover may alter a minority of specific gait parameters, although any reported detectable change appeared small, inconsistent and unpredictable.

Comparison 3: Regular footwear verses barefoot for people with diabetes and neuropathy

A single study⁵¹ compared regular footwear with walking barefoot, in 12 people with diabetes and neuropathy and eight controls matched for age, sex and BMI. The authors reported on nine different gait parameters recorded whilst participants walked over short (7m) and long (20m) distances. Participants were asked to bring the shoes they wore most often during activities of daily living. Most chose to wear either Oxford type footwear (approximately 40%) or new balance type footwear (approximately 60%) (Personal correspondence with the author). There was no difference in any of the gait parameters when regular footwear was worn over a short distance. Over the longer distance the diabetic neuropathic group displayed a significantly greater double support time (20%) when compared to the elderly control group. There was no significant difference in any of the gait parameters when regular footwear was worn over a long distance with the exception of coefficient of variation of gait velocity. Over the longer distances wearing shoes reduced the coefficient of variation of gait velocity in people with diabetes and neuropathy by 46% to a similar level to that seen in the controls when tested wearing shoes. There is limited evidence to suggest that wearing footwear over long distances increases the consistency of step to step velocity in people with diabetes and neuropathy to a level similar to that seen in elderly healthy people.

Comparison 4: Ankle foot orthosis verses no intervention for people with sensory perception loss

Ankle foot orthosis were compared to no intervention in 65 people with peripheral neuropathy in three studies^{24, 52, 53} reported in four publications.^{24, 52-54} Participants were diagnosed with a range of underlying long term conditions; 49 were diagnosed with diabetes, nine suffered idiopathic sensory loss, three with connective tissue disease, two the neuropathy originated from the toxic effect of medication, one was diagnosed with hypothyroidism, and one had a family history of neuropathy.

One study⁵² compared a plastic semi flexible sagittal plane AFO with no intervention in 11 people with sensory perception loss, seven of whom were diagnosed diabetic. The authors measured balance using the specifically designed dynamic postural system (EquiTest NeuroCom International Inc). The authors reported that the sensory organization scores calculated by the system significantly improved when the AFO was worn by 13% standing with eyes open, 35% standing with eyes closed, 39% standing on a rotating platform eyes open and 59% standing on a rotating platform eyes closed.

In a second study⁵³ the same research team appeared to repeat their 2006 study with a group of 12 people with diabetes and neuropathy. The authors reported that the sensory organization scores calculated by the dynamic postural system improved significantly with eyes closed but not with eyes open. The improvement recorded when the AFO was worn when standing on a static platform with eyes closed was 2%. The improvement recorded when the AFO was worn when standing on the rotating platform with eyes closed was 80%.

A third study²⁴ compared a medial lateral AFO with no intervention in 42 people with peripheral neuropathy, (30 with diabetes) whilst walking over irregular terrain under low light conditions. The authors reported a significant reduction in step width range (-28.4mm), step width variability (-3.8mm) and step time variability of (0.024 seconds) when the AFO was worn. Standard deviation (SD) was used as a measure of variability. However, it is unclear if the calculation was based on the SD of the total group score or the range of SDs taken from individual scores.

In a separate publication⁵⁴ the same research team present secondary analysis from their previous 2004 study using a sub sample of 20 females. The authors report that step length, as a fraction of body height, increased in this sub-group by 0.007 ($p < 0.001$) of 20 females when the AFO was worn. Comparisons of step length for the original total sample were not reported.

There is limited evidence to suggest that static balance and perturbed balance of people with sensory perception loss improves when a semi-flexible plastic sagittal plane AFO is worn, this improvement was greater when visual cues were removed. Evidence to suggest that medial lateral AFO reduces step to step variability and increases step length of people with sensory perception loss is very weak.

Discussion

The aim of this review was to highlight balance and gait deficits, and falls risk as a consideration for healthcare professionals prescribing foot and ankle interventions to people with pathological loss of foot sensation. The review sought to establish the therapeutic benefits of footwear interventions on laboratory and clinical measures of balance, mobility, and falls, within insensate clinical populations. The results of this review were intended to inform the direction of the development of new interventions, designed to enhance balance, gait and reduce falls in people with pathological sensory perception loss. Importantly, none of the included studies used the primary outcome (incidence or frequency) of falls as an outcome measure. A total of nine studies^{21, 22, 24, 26, 50-53, 55} reported secondary outcomes of balance and gait to assess the effectiveness of various foot and ankle devices in people with sensory perception loss. The results of these nine studies imply that whilst footwear and insole devices have the potential to modify the balance and gait of people with sensory perception loss, varying the softness/hardness of the insole does not appear to have an effect. The results are discussed below.

The effect of foot and ankle devices on people with long-term chronic conditions and sensory perception loss

Four of the studies were designed to include a control group. In all of these studies baseline balance and gait parameters were abnormal in participants with sensory loss when compared to controls.^{21, 22, 26, 51} However a comparison of intervention effect size between the participant groups within the four studies found the response to be similar (or enhanced within the group with sensory loss) regardless of sensory perception threshold. More specifically one study failed to detect a change in either participant group,²⁶ whilst a second found a comparable significant effect in both groups when the intervention was worn.²¹ A further two studies reported a significant change in a single outcome measure for participants with sensory loss but not healthy controls.^{22, 51}

The majority of studies investigating the effect of foot and ankle devices intended to improve balance

or gait, particularly through sensory enhancement, have excluded participants suffering sensory perception loss because the presumed mechanism of action was considered inapplicable.^{23, 59-62} In the absence of supporting evidence, such studies⁵⁹⁻⁶² presumed that insensate participants would be unable to detect the 'novel' design features (textured covers or vibrating components) intended to enhance sensory feedback and thus render the device ineffective. The findings of this review appear to challenge that rationale, conversely it appears that people with sensory perception loss may respond to foot and ankle devices and should be included in future research studies on the topic.

Therapeutic benefits of foot and ankle devices within clinical populations with sensory perception loss

Impairments in balance and gait performance are known risk factors for falls in ageing and clinical populations.^{35, 41, 42} Therefore, measures of postural sway during standing tasks, and changes in gait patterns, reported by several included studies,^{34, 35, 40} were considered surrogate measures of falls risk and therapeutic benefit in this review.

Change in gait patterns

The large variation in footwear and insole interventions prevented the pooling of study data. However, several of the included studies^{24, 26, 50, 51, 54, 55} investigated the effect of the various interventions on gait performance related measures. Thus some dialogue about the effect of the devices on parameters of gait for people with sensory perception loss can be made. There is limited evidence that for people with sensory perception loss; 1) The roughness and horizontal stretch/shift of the insole top cover may alter a minority of specific gait parameters (double stance time at gait initiation, some sagittal plane joint angles).^{50 55} 2) Wearing standard footwear over long distances may increase the consistency of step to step velocity to a similar level to that seen in elderly healthy people.⁵¹ 3) Medial lateral AFO may reduce step to step variability whilst increasing step length.⁵⁴ When considering the effect of the footwear and insole interventions investigated within these studies, some attention should be directed at the confounding effect of the wide range of host footwear worn by participants during data collection. Insoles worn within footwear, cannot work in isolation, but instead function in synergy with the footwear within which they are contained. Thus whilst most of the trials used standardized footwear,^{24, 26, 50, 54, 55} the large variation in the footwear design between studies prevents any direct comparison of effect or pooling of study data. For example one study chose to use leather lined sandals as the control,²⁶ to more closely reflect barefoot walking, whilst another provided athletic shoes with integral mechanical support and plantar cushioning.^{24, 54} A third study issued all participants with therapeutic extra depth footwear incorporating a semi-ridged rocker sole,⁵⁵ (a design feature known to impact upon gait). Yet another study asked participants to bring their own regular footwear to wear during data collection.⁵¹ It is clear that an agreed protocol (including guidance on the standardizing of footwear worn during the investigation of foot and ankle devices) is needed before trial data can be pooled and definitive conclusions made about footwear and insole intervention choice.

While foot and ankle devices, (particularly supportive footwear⁵¹ and ankle bracing^{24, 54}) offering mechanical support, may improve some aspects of gait (eg step consistency) which are considered to be relevant to falls risk, the immediate benefit is likely to be marginal. Equally, based on the available

evidence it would seem unlikely that people with sensory loss treated with foot and ankle devices, would experience any immediate adverse change to their gait pattern which would render them unsafe. It is possible that the footwear type and/or insole design features investigated (e.g. horizontal stretch/shift of top covers⁵⁵), may be useful in the management of factors other than gait and balance, in people with loss of foot sensation, such as prevention of ulceration and may be used without compromising gait stability.

Postural sway tests

Whilst the different types of foot and ankle orthosis were evaluated separately, an overall conclusion regarding the general effect of ankle and foot devices for people with sensory perception loss on postural sway can be discussed. There is some evidence that for people with sensory perception loss; 1) Vibrating insoles may improve static balance when other compensatory balance strategies are compromised (eg eyes closed, dual task).^{21, 22} 2) The properties of the top cover material (roughness, softness or horizontal stretch/shift) selected for insole fabrication does not affect static balance.^{21, 26, 50, 55} 3) A semi-flexible plastic sagittal plane AFO may improve static balance and perturbed balance and that this improvement is greater with visual cues removed.^{52, 53}

The results suggest that insole design can artificially alter the somatosensory awareness that contributes to the maintenance of postural stability in people with diabetes and neuropathy.^{21, 22, 52} It appears the application of mechanical stimuli, by way of vibratory components,^{21, 22} have a more definite effect on static balance performance, than insoles which alter only the material composition of the top cover.²⁶ Thus it may prove more effective to design insoles which stimulate the plantar receptors that detect vibration rather than those involved with light touch. In addition, the site of somatosensory stimulation may also be an important factor to consider in insole or orthotic design for people with loss of foot sensation. Interventions which extend across both the foot and ankle regions (e.g. AFOs)^{52, 53} appear to have a more pronounced effect on balance measures than interventions which target only the plantar surface of the foot. The results of this systematic review suggest that the usefulness of footwear and insole interventions designed to enhance plantar sensory input may become more apparent when the residual sensory systems for balance control are manipulated, for example removing vision by closing the eyes. Under such conditions, individuals with loss of foot sensation appear to show greater reliance on and awareness of an altered somatosensory input, possibly as a consequence of induced sensory re-weighting.

Variations in insole design do not appear to have a large or consistent effect on the gait, over short distances, of people with sensory perception loss. The gait pattern is in part dependent on the planning, transmission and response of the descending motor command, confounded by a number of contributing variables including visual acuity, level of motivation and concentration, muscle strength, and cognitive function. Thus it is unsurprising to find the spatial and temporal parameters of gait are not a sensitive measure of the afferent feedback or mechanical support provided by interventions included in this review. There is insufficient evidence within the included studies to determine if the magnitude of effect of foot and ankle devices on balance and gait in people with sensory perception loss is clinically beneficial.

Limitations of the review

The findings of this review were limited because of the small number of studies meeting the inclusion criteria, the poor methodological quality of those studies, the inability to be able to pool the results and the inadequate sample size meaning most studies were underpowered. Moreover, only studies reported in English were included. This may have resulted in the exclusion of studies that were relevant and thus important for this review. Qualitative studies were excluded from the review and these studies may have been able to contribute to the feasibility aspects of wearing/using the foot and ankle devices.

Conclusion

Implications for practice

Based on the evidence analyzed in the review the following recommendations are considered important when prescribing foot and ankle devices for people with sensory perception loss. Levels of evidence and grades of recommendation have been assigned to each recommendation according to the JBI levels of evidence (Appendix VII). These recommendations should be interpreted with caution because the information provided by the studies included in this review was insufficient to determine with certainty if the observed effect might be reflected in clinical practice.

- The existing evidence does not reveal any disadvantage to balance or gait from using compliant covers in preference to hard covers for people with sensory perception loss. Thick cushioned covers should still be used on insoles to protect the feet of people at risk of neuropathic foot ulceration without increasing risk of falls (JBI level 3 evidence, Grade B recommendation).
- Foot and ankle devices can improve static balance and consistency of walking of people with sensory perception loss, most probably through a combination of mechanical support and increased somatosensory awareness. However, a clear recommendation regarding device selection cannot be made at this time (JBI level 3 evidence, Grade B recommendation).

Implications for research

This review has identified several potential areas for future research to advance the development of foot and ankle interventions that enhance balance and gait and reduce falls risk in people with sensory perception loss.

- Based on the available evidence it is highly plausible that the mechanism by which foot and ankle devices affect the standing balance and gait kinematics of people with sensory perception loss is through a combination of mechanical support and adjustment of sensorimotor control. Thus both approaches have potential to play a role in reducing falls risk and should therefore be considered viable for future foot and ankle device development and design.
- The results of this review seem to suggest that the effect of foot and ankle devices on static balance may be enhanced when eyes are closed and people with sensory perception loss are forced to rely more on their somatosensory systems for postural balance control. This observation may have

inferences to suggest how insoles might be utilized as a training aid in the development of balance sensory re-training programmes.

All of the included trials have methodological limitations that expose the trial findings to a high risk of bias. All of the trials were pre-clinical lab based studies designed to test a hypothesis in a single data collection session. This research design precludes the use of falls as an outcome measure, instead forcing researchers to base conclusions on surrogate measures of balance and gait known to be associated with falls risk. None of the trials were randomized controlled trial design. Most studies were underpowered. Several studies did not use a control group, and none randomized the intervention or blinded to the procedure. All studies only looked at the immediate effect and most were laboratory based proof of concept studies.

Despite this further basic science is warranted to increase our understanding of:

- The pathophysiology of balance impairment and the potential for the manipulation of subsequent postural compensation strategies adopted by people with sensory loss.
- The mechanism of action of different intervention designs to determine which devices are actually bringing about their effects by way of an underlying sensory mechanism, as theorized (e.g. measuring EEG activity, fMRI studies).

In addition to make a decision on best practice, interventions need to be tested in robust randomized controlled trials outside of the laboratory and within the clinical setting over an extended follow up period. To ensure clinical relevance and utility the follow up period should be a sufficient to capture differences in incidence or frequency of falls and explore aspects of intervention adherence.

Further clinical research is required using sound methodologies which examines different elements such as:

- Comparison of a range of devices with differing mode of action, (mechanical support and altered sensorimotor control).
- Longevity, durability and user acceptability of foot and ankle devices.
- Long term clinical effects of foot and ankle devices.
- Economic and health burden evaluation of footwear intervention.
- Patient perception of changes in fear of falls, balance confidence and quality of life.
- The effectiveness of devices in chronic long term conditions for example people with diabetic sensory neuropathy or multiple sclerosis and groups with different levels of severity of sensory perception loss.

Outcome measures should include incidence or frequency of falls, intervention adherence levels, and adverse effects (e.g. skin damage due to prolonged wear of a device). To increase the clinical relevance of clinical trials investigating this topic area and targeting people at increased risk of foot ulceration, a secondary outcome measure of peak pressure reduction as an indicator of foot ulcer risk is recommended.

Conflict of interest

The authors had no conflict of interest to declare.

Appendix V: Excluded studies and reasons for exclusion

1. Bregman D, De Groot V, Van Diggele P, Meulman H, Houdijk H, Harlaar J. Polypropylene ankle foot orthoses to overcome drop-foot gait in central neurological patients: A mechanical and functional evaluation

Reason for exclusion: Unable to contact author. Unclear if the three MS participants were neuropathic.

2. Cattaneo D, Marazzini F, Crippa A, Cardini R. Do static or dynamic AFOs improve balance?

Reason for exclusion: Unable to contact author. participants not obviously tested for neuropathy

3. Creylman V, Muraru L, Pallari J, Vertommen H, Peeraer L. Gait assessment during the initial fitting of customized selective laser sintering ankle foot orthoses in subjects with drop foot

Reason for exclusion: Pathology and therefore any neuropathy unilateral

4. Dixon J, Hatton A, Robinson J, Gamesby-Iyayi H, Hodgson D, Rome K, Warnett R, Martin D. Effect of textured insoles on balance and gait in people with multiple sclerosis: An exploratory trial

Reason for exclusion: Majority of participants were not neuropathic

5. Dufek J, Neumann E, Hawkins M, O'Toole B. Functional and dynamic response characteristics of a custom composite ankle foot orthosis for Charcot-Marie-Tooth patients

Reason for exclusion: Authors contacted: Did not check for sensory perception loss

6. Farmer S, Pearce G, Whittall J, Quinlivan R, Patrick J. The use of stock orthoses to assist gait in neuromuscular disorders: a pilot study

Reason for exclusion: Age range from 14 years. Not neuropathic

7. Grewal G, Bharara M, Talal R, Talal K, Armstrong D, Najafi B. Diabetic Peripheral Neuropathy and Gait: Does Footwear Modify This Association?

Reason for exclusion: Authors contacted: Unable to differentiate data from participants with diabetic peripheral neuropathy wearing footwear and those in cast/offloading sandals. Excluded after critical appraisal as the allocation of the intervention group was unclear.

8. Guillebastre B, Calmels P, Rougier P. Assessment of appropriate ankle-foot orthoses models for patients with Charcot-Marie-Tooth disease

Reason for exclusion: No clear identification of pathological sensory loss. Not able to distinguish between neuropathic and non-neuropathic participants

9. Jenkins M, Almeida Q, Spaulding S, van Oostveen R, Holmes J, Johnson A, Perry S. Plantar cutaneous sensory stimulation improves single-limb support time, and EMG activation patterns among individuals with Parkinson's disease

Reason for exclusion: Exclusion criteria not neuropathic

10. Kalron A, Pasitselsky D, Greenberg-Abrahami M, Achiron. A. Do textured insoles affect postural control and spatiotemporal parameters of gait and plantar sensation in people with Multiple Sclerosis?

Reason for exclusion: Inclusion criteria less than 5.07 monofilament thus not all participants meet

neuropathic criteria

11. Maki B, Perry S, Norrie R, McIlroy W. Effect of facilitation of sensation from plantar foot-surface boundaries on postural stabilization in young and older adults

Reason for exclusion: No pathological Sensory perception loss

12. McLoughlin J, Barr C, Sturnieks D, Lord S, Crotty M. Effect of wearing a dorsiflexion assist orthosis on mobility, perceived fatigue and exertion during the six-minute walk test in people with multiple sclerosis: a randomised cross-over protocol

Reason for exclusion: Protocol only. Author contacted; trial has now been completed and published but no measures of foot sensation were taken.

13. McLoughlin J, Lord S, Barr C, Crotty C, Sturnieks D. Dorsiflexion assist orthosis reduces the physiological cost and mitigates deterioration in strength and balance associated with walking in people With multiple sclerosis

Reason for exclusion: Participants not tested for neuropathy

14. Perry S, Radtke A, McIlroy W, Fernie G, Maki B. Efficacy and effectiveness of a balance-enhancing insole

Reason for exclusion: Although vibration perception levels appear normal for elderly people. Not pathological sensory loss

15. Priplata A, Niemi J, Harry J, Lipsitz L, Collins J. Vibrating insoles and balance control in elderly people

Reason for exclusion: Not pathological sensation loss. Sensation loss within normal limits for elderly population

16. Qiu F, Cole M, Davids K, Hennig E, Silburn P, Netscher H, Kerr G. Effects of textured insoles on balance in people with Parkinson's disease

Reason for exclusion: Author contacted; Participants not assessed for sensation loss

17. Ramdharry G, Marsden J, Day B, Thompson A. De-stabilizing and training effects of foot orthoses in multiple sclerosis

Reason for exclusion: Author contacted; Participants not tested for neuropathy

18. Ramdharry G, Pollard A, Marsden J, Reilly M, Comparing gait performance of people with Charcot-Marie-Tooth disease who do and do not wear ankle foot orthoses

Reason for exclusion: Unclear if pathological sensation loss: light touch score would suggest neuropathy vibration at hallux would suggest not

19. Sheffler L, Hennessey M, Knutson J, Naples G, Chae J. Functional effect of an ankle foot orthosis on gait in multiple sclerosis: A pilot study

Reason for exclusion: Subjects were excluded for absent sensation in the ipsilateral lower limb,

20. Son J, Ashton-Miller J, Richardson J., Do ankle orthoses improve ankle proprioceptive thresholds or unipedal balance in older persons with peripheral neuropathy?

Reason for exclusion: Poor quality: Both reviewers considered outcome measures as unreliable. This study was excluded after critical appraisal.

21. Stevens V, Goodman K, Rough K, Kraft G. Gait Impairment and Optimizing Mobility in Multiple Sclerosis

Reason for exclusion: Discussion of the literature

22. Wegener C, Wegener K, Smith R, Schott C, Burns J. Biomechanical effects of sensorimotor orthoses in adults with Charcot Marie Tooth disease

Reason for exclusion: Authors contacted not all participants neuropathic

23. de Morais Barbosa C, Barros Bertolo M, Marques Neto J, Bellini Coimbra I, Davitt M, de Paiva Magalhaes E. The effect of foot orthoses on balance, foot pain and disability in elderly women with osteoporosis: a randomized clinical trial

Reason for exclusion: Exclusion criteria were reduced tactile and thermal foot sensibility

Appendix VI: List of study findings/conclusions/characteristics of included studies

MAStARI

Study	Methods/outcome measure	Participants	Intervention	Findings/conclusions	Notes
<p>Hijmans J, Geertzen J, Zijlstra W, Hof A, Postema K. 2008²²</p>	<p>Repeated measure random order case comparison study</p> <p>Force plate stabilometry.</p> <p>Mean velocity of COP displacement in mm per sec.</p> <p>Root mean square of anterior posterior and medial lateral COP vel.</p>	<p>Group A: People with diabetes and neuropathy. n=17 8/9 M/F 52.1 years +/-6 between 40 and 60 years</p> <p>Group B: People without diabetes. n=15 7/8 M/F 51.8yrs +/-5.6</p> <p>Exclusion Group A: ulceration, amputation unable to stand without an aid, musc disorder, visual impairment</p> <p>Exclusion Group B: DM, monofilament, tuning fork 0</p>	<p>Intervention: Vibrating insoles set at 90% of the tactile threshold for each individual (or maximum amplitude (120v) where the threshold could not be reached.</p> <p>The vibration insoles consist of a cork sole with three built-in piezoelectric elements at MTP1, MTP5 and the heel. The sole was then covered with a thin leather layer.</p> <p>Control: Vibrating insoles turned off.</p> <p>X 5 60 second trials 1st and 5th with eyes open. Other 3 with 1. Eyes closed 2. Dual task 3. Both presented in random order.</p>	<p>Both groups sway increased with eyes closed and dual task (p=0.01).</p> <p>Addition of vibration made no diff to non-diabetic group for all conditions</p> <p>Addition of vibration made no diff to diabetic neuropathic group except eyes closed plus dual task when velocity of COP displacement decreased and the root mean square displacement of COP vel AP (not ML) decreased from 24.3 +/-3.3 to 20.4 +/-20.4 mm/s (p=0.05).</p> <p>Use of vibration insoles may only be helpful for people with diabetes and neuropathy unable to use other compensatory strategies.</p>	<p>71% of subjects with neuropathy used the max amplitude of vibration (120v) but not sufficient to reach the sensory detection threshold.</p> <p>Participants were below 60 years to guard against sensory loss due to normal aging being a feature of the control group.</p> <p>Outcome measures chosen were static measures of balance not necessarily representative of dynamic function.</p> <p>Only the immediate effect of the insole on COP measures investigated no longitudinal investigation undertaken.</p> <p>Authors contacted to</p>

Study	Methods/outcome measure	Participants	Intervention	Findings/conclusions	Notes
			Vibration turned on for 30 secs off for 30 seconds. First 5 seconds discarded.		supply mean velocity of COP displacement data not available from the publication. Author replied not able to locate the information.
<p>Kelleher K, Spence W, Solomonidis S, Apatsidis D. 2010⁵⁰</p>	<p>Repeated measure random order case comparison study</p> <p>EMG. kinematic and kinetic parameters during gait.</p> <p>Sagittal plane ankle, knee and hip angles.</p> <p>Gait velocity (m/s), cadence (steps/min), ground reaction force (N/kg).</p> <p>EMG activity; tibialis anterior, medial gastrocnemius lateral gastrocnemius soleus (% peak amplitude)</p>	<p>Group A: Fourteen people with either relapsing-remitting or secondary progressive MS and sensation loss. 41.8+/-7.3. Male to female ratio 4:3</p> <p>Group B: Same group without insoles</p> <p>Group C: 10 healthy age and weight matched volunteers walking without insoles and used only as a point of reference.</p> <p>MS Participants were included if they could walk 25 feet in 20 seconds or less with or without unilateral</p>	<p>Intervention: Fine leather insoles with grade p80 wet and dry sandpaper adhered to the top, in flat shoes without socks.</p> <p>Control: No insoles</p> <p>Participants walked a distance of 6 m at a self-selected walking velocity. Gait trials were repeated until three trials with a clean strike of the force plate were achieved for each leg with and without insoles. Trials with and without insoles were randomized.</p>	<p>There was no significant difference in gait velocity or cadence between groups A and B.</p> <p>There were no differences between Group A and B in kinematic parameters except an increase in ankle joint dorsiflexion from 13.3 +/- 5.3 to 13.9 +/- 13.9 degrees (p<0.05), and increase in total knee excursion angle from 67.5 +/-6.1 to 68.9+/- 6.1 degrees (p=0.05) and total hip excursion angle from 42.0 +/- 6.5 to 42.8 +/- 5.7 degrees (p<0.05).</p> <p>There were no differences between Group A and B in EMG activity except an increase in lateral gastrocnemius during the first phase of gait (heel strike to the first peak of</p>	<p>Unaware if the authors controlled for footwear.</p> <p>There is only one set of data presented for the control group. The control group data is not used in the analysis but inserted as reference data only. It appears that only no insole data was collected for the control group.</p>

Study	Methods/outcome measure	Participants	Intervention	Findings/conclusions	Notes
		<p>support.</p> <p>Sensation loss threshold was determined using a forced -choice technique at three locations on the plantar aspects of both feet; the heel medial and lateral forefoot. The tactile threshold was defined as the lightest filament that could be felt more than 50% of the time.</p> <p>Sensory threshold at medial forefoot: MS group 5.71 +/- 0.85, Control group 3.77 +/- 0.25.</p>		<p>vertical GRF) from 25.94 +/- 12.95 to 27.93 +/- 13.41 and increase in medial gastrocnemius during phase 3 of gait (swing) from 15.19 +/-7.79 to 16.37 +/- 8.93 (p<0.05).</p> <p>The increase in EMG activity of the shank muscles was non-significant with the exception of lateral gastrocnemius in phase one of gait. Thus the authors conclusions regarding changes in muscle activity with the introduction of a textured insole must be considered with caution.</p> <p>Increase in sagittal plane joint angles with the introduction of the insole were largely non-significant. Where a significant difference was found the change was small, 2 degrees or less. An insole effect this small may not have clinical relevance and thus must be considered with caution.</p>

Matched for age sex and BMI.</p> <p>People were excluded with foot ulceration or orthopaedic or surgical problems influencing gait or were unable to walk without a waking aid or had history of non-</p>	<p>Intervention: Participants regular shoes. Mainly prescribed diabetic shoes according to guideline of prescribed diabetic shoes in USA.</p> <p>Control: Barefoot</p> <p>Group B: also were asked to wear their regular shoes. Subjects were asked to bring the regular shoes, they wear most often during activities of daily living but not sandal/flip flop or high heels.</p> <p>Most chose to wear either oxford type footwear (approximately 40%) or new balance type footwear (approximately 60%).</p> <p>Participants were asked to walk at a self-selected speed</p>	<p>Most differences in barefoot and shoe conditions were comparable between Group A and B.</p> <p>Over short walking distances these differences did not reach a level of significance.</p> <p>Over a longer distance wearing shoes reduced the coefficient of variation of gait velocity in Group A by 46 %, from 4.04 +/- 2.2 to 2.2 +/-1.3 % (p=0.02) to a level similar to that seen in Group B when tested wearing shoes.</p> <p>Over the longer distance double support time was 20% (p=0.03) greater in group A (barefoot; 25.5 +/- 7.0, shoe 26.0 +/- 4.9) when compared to Group B (barefoot 20.3 +/- 5.1, shoe 20.9 +/- 4.9) both with and without shoes.</p> <p>Gait unsteadiness may be improved in people with diabetes and neuropathy by wearing shoes.</p>	<p>Data collected dynamically outside the confines of the gait laboratory.</p> <p>Footwear was not standardized but rather participants wore their regular shoes.</p>

Study	Methods/outcome measure	Participants	Intervention	Findings/conclusions	Notes
	steady state.	diabetes related peripheral neuropathy	for a short distance 7 meters and a long distance 20 meters barefoot and in their regular shoes. Each trial was performed twice and the testing order was randomized.	This improvement may only be apparent over longer walking distances (>20meters).	
Priplata A, Patriitti B, Niemi J, Hughes R, Gravelle D, Lipsitz L, Veves A, Joel Bonato P, Collins, J. 2006 ²¹	<p>Repeated measure random order case comparison study</p> <p>Postural sway measured using a marker attached to right shoulder used to record shoulder displacement.</p> <p>Parameters included mean and max stabilogram radius, area of stabilogram, range of anteroposterior and medial-lateral discursion.</p>	<p>Group A; 15 patients with moderate diabetic neuropathy vibration perception threshold between 20 and 40 htz. (9 female and 6 male age range 38-81 years mean age 60 +/- 11years (SD).</p> <p>Group B; 12 healthy elderly subjects from a previous study. (8 female and 4 male age range 68-78 years mean age 73 +/- 3 years.</p>	<p>Intervention: Viscoelastic silicone insole with pre-sensory threshold vibrating elements turned on.</p> <p>Control: Vibrating insoles turned off</p> <p>Participants asked to stand with eyes closed to remove visual cues. 30 secs stance. 10 trials 5 with/without noise.</p> <p>2 mins seated break middle of test.</p>	<p>Sway parameters decrease with noise (p<0.05).</p> <p>No differential effect between patient groups (people with diabetes and neuropathy and the elderly)</p> <p>Reduction in postural sway during the application of noise appears greater in individuals with larger baseline postural sway.</p> <p>Wearing vibrating insoles appears to reduce sway in people with eyes closed even in those with diabetes and moderate sensory perception loss.</p>	<p>Participant groups were not matched for age or sex.</p> <p>20-40v moderate PDN defined by American Diabetes Association Expert Committee. Also exclude patients with severe neuropathy who would have functional loss of peripheral nerve function.</p> <p>Reflective marker to the right shoulder unusual method of recording sway. Authors claim that data captured in this way highly correlated with foot centre of pressure displacement data.</p>

Study	Methods/outcome measure	Participants	Intervention	Findings/conclusions	Notes
					<p>Limited transferability of finding to clinical practice.</p> <p>Only eyes closed condition recorded. Effect of insoles with eyes open unknown. Insoles not yet designed for in shoe use.</p> <p>Detailed data sets and pairwise comparisons not published.</p>
<p>Rao N, Aruin A. 2006 ⁵²</p>	<p>Repeated measure random order case comparison study.</p> <p>Static and dynamic balance measured using the dynamic postural system (EquiTest, NeuroCom International Inc.) This system consists of a series of tests performed on a platform whilst displacement of the centre of gravity is measured and</p>	<p>Group A: Eleven people with sensory perception loss. M/F 6/5. Age 56.1 +/- 7.7 years with a range of 46-68 years.</p> <p>Mean time since peripheral neuropathy diagnosed 11.0 +/- 9.9 years with a range of 1-35 years.</p> <p>Seven patients</p>	<p>Intervention: Ankle foot orthosis. AFO consisted of a single continuous piece of plastic 4.5 mm thick extending to the sulcus of the toes and 25mm distal to the fibular head providing auxiliary sensory cues and additional mechanical support.</p> <p>Control: No ankle foot orthosis.</p>	<p>All four sensory organization test scores increased when by a significant amount when the AFO was worn (p<0.01). Standing still with eyes open the score increased from 80.41 +/- 5.65 to 91.41 +/- 1.12 when the AFO was worn, the increase with eyes closed was 48.86 +/- 8.52 to 66.23 +/- 7.19. Standing on the rotation platform with eyes open the score increased from 53.00 +/- 8.23 to 73.68 +/- 5.77 when the AFO was</p>	<p>Participants acted as their own controls.</p> <p>Changes in strength did not reach statistical significance when the with and without AFO conditions were compared.</p> <p>Authors did not appear to test for neuropathy proximal to the foot therefore an assumption is made that sensation is intact in the lower extremity.</p>

Study	Methods/outcome measure	Participants	Intervention	Findings/conclusions	Notes
	<p>automatically compared to a database of healthy controls.</p>	<p>were diabetic, four had neuropathy not associated with diabetes.</p> <p>Neuropathy determined using monofilaments applied to three dorsal and two plantar foot zones. Correct detection of light touch by a filament in three out of five trials was considered to be that subjects sensory threshold. Average score for the group 4.6 +/- 1.19</p>	<p>Sensory organization test. 4 tests including eyes open and closed with the platform stationary and rotating in the anterior posterior direction. Each test is given a score out of 100. A higher score signifies less sway.</p> <p>Motor Control Test 4 tests including medium and large forward and backward perturbations of the platform. Latency equals time in milliseconds between the onset of translation and the onset of the subjects active response and the support surface movement and strength, the amount of force generated by each leg during the automatic postural response.</p>	<p>worn, the increase with eyes closed was 20.00 +/- 7.2 to 31.90 +/- 7.52.</p> <p>There was a significant difference in latency but not muscle strength when the AFO and no AFO conditions were compared.</p> <p>Authors suggest that the increase in sensory organization test scores and whilst wearing the AFO indicates an improvement in static postural balance.</p> <p>Furthermore the improvement in latency score suggests a possible improved response to a perturbation.</p>	<p>Only immediate effect of AFO investigated.</p> <p>Difficult to give scale or meaning to the degree of improvement seen with the addition of the AFO because the apparatus used is unusual and the outcome recorded without recognizable measurement units.</p>

Study	Methods/outcome measure	Participants	Intervention	Findings/conclusions	Notes
<p>Rao N, Aruin A. 2011⁵³</p>	<p>Repeated measures, within-subjects comparison:</p> <p>Sensory organization test and response to platform perturbations, with and without intervention.</p>	<p>Group A; Twelve adults with diabetes and peripheral neuropathy. Age 69.5 +/- 14.1 years. M/F 9:3.</p> <p>Included with clinically confirmed diabetes, peripheral neuropathy, and loss of muscle stretch reflexes. All able to walk independently (with or without assistive device) and stand unassisted for 5 minutes. No other major medical conditions that can affect balance.</p>	<p>Intervention: Ankle foot orthoses (worn bilaterally) providing auxiliary sensory information to the calf via the shank of the brace and to the middle of the tibia via calf straps but without mechanical support.</p> <p>Control: No ankle foot orthoses.</p> <p>Sensory organization test as previously described.</p> <p>Motor control test. Data for latency but not strength presented.</p>	<p>Post hoc analysis showed a significant improvement in sensory organization scores with the addition of the AFO when participants were tested standing still with eyes closed (85.29 +/-10.97 without AFO, 86.80 +/- 0.88 with AFO) and sway referenced support with eyes closed 21.16 +/- 6.40 without AFO and 38.29 +/- 7.29 with AFO), but not eyes open (p<0.05).</p> <p>There was no significant difference in latency scores when participants wore the AFO (p=0.20).</p> <p>Applying auxiliary sensory information to the calf and tibia appears to improve standing balance in people with diabetic neuropathy with eyes closed, but not with eyes open, and does not appear to improve reactive responses to platform perturbations.</p>	<p>Participants wore standardized footwear.</p> <p>Participants acted as their own controls. Changes in strength did not reach statistical significance when the with and without AFO conditions were compared.</p> <p>Authors did not appear to test for neuropathy proximal to the foot therefore an assumption is made that sensation is intact in the lower extremity.</p> <p>Only immediate effect of AFO investigated.</p> <p>Difficult to give scale or meaning to the degree of improvement seen with the addition of the AFO because the apparatus used is unusual and the outcome recorded without recognizable measurement units.</p>

Study	Methods/outcome measure	Participants	Intervention	Findings/conclusions	Notes
<p>Richardson J, Thies S, Ashton-Miller J. 2008 ⁵⁴</p>	<p>Repeated measures, within-subjects comparison</p> <p>Step length.</p>	<p>Group A: Twenty women with peripheral neuropathy not necessarily of diabetic origin. Mean age 64.5 (SD +/- 9.7) years. Mean BMI 32.1 +/- 6.9. Subgroup of a previous study 2004</p>	<p>Intervention: Ten walking trials (over an irregular surface) wearing a medial/lateral ankle brace. (Active Ankle Systems Inc Louisville. KY) consisting of foam lined shells secured to the medial and lateral aspects of the ankle and lower leg.</p> <p>Control: Ten walking trials with no intervention (over a smooth and irregular surface).</p>	<p>Available published data relating to the effect of the AFO is limited to step length as a fraction of body height whilst walking on irregular surface.</p> <p>Step length increased when the AFO was worn from 0.269 +/- 0.044 to 0.276 +/-0.045 (p<0.001). The intervention gave lateral ankle support suggesting that greater frontal plane stability allowed step length to increase.</p>	<p>The only data presented for the effect of the intervention is for step length. Whilst this was statistically significant, the between-condition difference was very small (question clinical significance).</p> <p>Further analyses were performed to explore correlations between step time variability and step length when using the interventions (on the irregular surface, and smooth [control no interventions] surface).</p> <p>This study compared the ankle brace condition with a walking cane and touching a vertical surface. Analysis of these additional interventions are outside the scope of this review and therefore will not be included.</p>

Study	Methods/outcome measure	Participants	Intervention	Findings/conclusions	Notes
					<p>Unclear if the AFO was providing sensory function, improved mechanical support or both.</p> <p>Participants were not blind to the intervention.</p>
<p>Richardson J, Thies S, DeMott T, Ashton-Miller, J. 2004 ²⁴</p>	<p>Repeated measure random order case comparison study</p> <p>Gait parameters including step-width variability and range, step-time variability, and speed.</p> <p>Variability measured using SD and range. Mean number of steps between 40 and 50.</p>	<p>Group A: 42 people with peripheral neuropathy (20 female) mean age 65.9 (SD +/- 9.7) years. Mean BMI 32.1 +/- 6.9</p> <p>Peripheral neuropathy was presumed caused by diabetes mellitus (n=30) idiopathic (n=5) connective tissue disease (n=3) toxic effect of medication (n=2) hypothyroidism (n=1) familial (n=1).</p>	<p>Intervention: Ten walking trials (over an irregular surface) wearing a medial/lateral ankle brace. (Active Ankle Systems Inc Louisville. KY) consisting of foam lined shells secured to the medial and lateral aspects of the ankle and lower leg.</p> <p>Control: Ten walking trials with no intervention (over a smooth and irregular surface).</p>	<p>When participants wore the AFO step width variability reduced from 41.0 +/- 1.5 to 37.2 +/- 1.3 mm (p=0.0024). Step width range reduced from 192.7 +/- 7.4 to 164.3 +/-7.4mm (p=0.038). Step time variability reduced from 0.073 +/- 0.005 to 0.049 +/- 0.005 seconds (p<0.001).</p> <p>No significant difference in gait speed with the addition of an AFO.</p> <p>The AFO may have improved dynamic balance in the frontal plane.</p>	<p>This study compared the ankle brace condition with a walking cane and touching a vertical surface. Analysis of these additional interventions are outside the scope of this review and therefore will not be included.</p> <p>Unclear if the AFO was providing sensory function, improved mechanical support or both.</p> <p>Participants were not blind to the intervention.</p>
<p>Wrobel J, Ammanath P, Le</p>	<p>Cross-sectional, repeated measures,</p>	<p>Group A: 27 subjects with</p>	<p>Intervention: Dynamic foot</p>	<p>There was a significant reduction in double stance</p>	<p>This study compared new intervention with</p>
